CHAPTER 1
Introduction 13

CHAPTER 2
Non-enzymatic glycation of proteins; a review 21
2.1 The glycation reaction 21
2.2 Non-enzymatic glycation of haemoglobin 23
   1 History 23
   2 Methods for quantitation of glycated haemoglobin 25
   3 Effect of glycation on the haemoglobin function 25
   4 Clinical applications of the measurement of glycated haemoglobin 25
      1 Glycated haemoglobin and glycaemic control 26
      2 Glycated haemoglobin measurement as a screening test for impaired glucose tolerance and diabetes mellitus 28
      3 Glycated haemoglobin and pregnancy 30
2.3 Non-enzymatic glycation of serum proteins 33
   1 History 33
   2 Methods for quantitation of glycated serum proteins 34
   3 Effect of glycation on function and metabolism of serum albumin 34
   4 Interferences in the measurement of glycated serum proteins 35
      1 Effect of protein concentration and protein composition on the measurement of glycated serum proteins 35
      2 The influence of protein half-life on the concentration of glycated serum proteins 36
      3 Influence of age and sex on the concentration of glycated serum proteins 36
   5 Clinical applications of glycated serum protein measurements 37
      1 Glycated serum proteins and glycaemic control 38
      2 Glycated serum protein measurement as screening test for impaired glucose tolerance and diabetes mellitus 40
      3 Glycated serum proteins and pregnancy 42
2.4 Non-enzymatic glycation of other proteins 44
CHAPTER 3
The fructosamine assay
3.1 Principle of the fructosamine assay 59
3.2 Measurement of the serum fructosamine concentration 59
3.3 Evaluation of the assay
   1 Linearity of the assay; effect of dilution of the sample 60
   2 Assay precision 61
   3 Effect of freezing, thawing, and long-term storage on the fructosamine concentration 62
3.4 Sensitivity to rapid glycaemic change 62
3.5 The influence of variations in the albumin or total protein concentration on the serum fructosamine concentration 63

CHAPTER 4
Comparison of fructosamine, glycated haemoglobin and postprandial blood glucose concentrations as measures of glycaemic control in non-insulin dependent diabetics 67

CHAPTER 5
The value of fructosamine and haemoglobin A1c measurements for screening and diagnosis of impaired glucose tolerance, diabetes mellitus and gestational diabetes 79

CHAPTER 6
Fructosamine and glycated haemoglobin in normal pregnancy 91

CHAPTER 7
The value of fructosamine measurement for the prediction of hyperglycaemia-related adverse neonatal outcome and large-for-gestational-age births 101

CHAPTER 8
Summary and conclusions 125
Samenvatting en conclusies 129

Curriculum vitae 133
Voorwoord

Het in dit proefschrift beschreven onderzoek is uitgevoerd binnen de afdeling Obsttrie van het De Wever Ziekenhuis te Heerlen in samenwerking met het Klinisch Chemisch Laboratorium en de afdeling Interne Geneeskunde van dit ziekenhuis.

Bij het tot stand komen van dit proefschrift was de hulp van velen onontbeerlijk. Zonder anderen teëort te willen doen, wil ik met name bedanken:
Prof.Dr.P.J. Brombacher en Dr.M.P. Van Dieijen-Visser die de initiators en katalysators waren van de studie. De realisatie van dit proefschrift is voor een belangrijk deel aan hen te danken.
Dr.L.L.H. Peeters die een essentiële bijdrage leverde aan de verwerking en analyse van de onderzoeksgelijkees van de zwangeren en het manuscript tevens enkele malen heeft "gescreend", zoals hij placht te zeggen. Zijn uitzonderlijke inzet waardeer ik ten zeerste.
Dr.L.A. Schellekens en Prof.Dr.J. de Haan die beiden op een eigenzinnige manier een belangrijke bijdrage geleverd hebben aan mijn opleiding tot gynaecoloog, mij hebben gestimuleerd tot het doen van onderzoek en mij bovendien de mogelijkheid hebben gegeven om dit proefschrift te schrijven.
De leden van de beoordelingscommissie (Prof.Dr.J.A. Flendrig, Prof.Dr.H.C. Hemker, Prof.Dr.M.J.N.C. Keirse, Prof.Dr.R.H. Kuijten en Prof.Dr.E.A. van der Veen) voor de kritische beschouwing van het manuscript en hun waardevolle adviezen.
De verpleegkundigen van de verloskamer en afdeling obsttrie die te allen tijde bereid waren bij patiënten bloed af te nemen en tevens noodzakelijke gegevens verzamelden.
Het personeel van de polikliniek wist steeds weer de zwangeren te motiveren hun medewerking te verlenen aan het onderzoek.
De medewerkers van het klinisch chemisch en haematologisch laboratorium, in het bijzonder mevrouw S.H.C.M. Joosten-Deckers en de heer G.J. Marell voor het nauwgezet coördineren van de analyse van de vele bloedmonster.
Dr.J. van Pelt, mevrouw M.L.F. Poetschlag-Sieler en mevrouw C.M. Lamine voor het verzorgen van de opmaak van diverse figuren en tabellen.
Dr.J.W.J. Van Wersch onder wiens leiding de bepalingen van geglyeerde haemoglobine werden uitgevoerd.
Dr.B.I. Davies die het manuscript taalkundig corrigeerde.
De patiënten die hun medewerking aan het onderzoek verleenden.
Tenslotte de leden van de maatschap (Dr.J.M.H. Ubachs, Dr.J.E.G.M. Stoot, J.A. Zandvoort, J.E.M. Degen en Dr.M.J. Heineman), die mij in woord en daad steunden.

In order to prevent the development of diabetic complications, maintenance of normoglycaemia is crucial. Several controlled prospective trials have provided evidence that long-term near normoglycaemia appears to prevent both severity and progression of late diabetic complications (The Steno Study: Deckert et al., 1983; The Oxford Study: Holman et al., 1983; The Dallas Study: Raskin et al., 1983; The Oslo Study: Dahl-Jörgensen et al., 1986). In the treatment of non-pregnant diabetics it is recommended to aim for fasting venous plasma glucose concentrations between 3.9 and 6.6 mmol/l, corresponding with the normal glucose range in non-diabetics. Furthermore, peaks after meals should not exceed 11.1 mmol/l (WHO Report, 1985).

Both in known diabetic patients who become pregnant (pregnant diabetics) and in gestational diabetics, maintenance of normoglycaemia improves foetal outcome (O’Sullivan et al., 1973; Gabbe et al., 1977; Coustan and Imanrah, 1984). More specifically, normoglycaemia in the embryonic period of diabetic pregnancy decreases the incidence of congenital anomalies (Chung and Myrianthopoulos, 1975; Miller et al., 1981; Fuhrmann, 1984), whereas in the second and third trimesters it diminishes the risk of perinatal morbidity and mortality (Karlsson and Kjellmer, 1972; Landon et al., 1987). Optimal treatment of gestational diabetics and pregnant diabetics is best served by maintenance of fasting blood glucose levels between 3.3 and 5.6 mmol/l with two-hour post-prandial values of less than 7.8 mmol/l (WHO, 1985; Gillmer et al., 1975).

From the above, it follows that, in order to minimize the risk of typical complications, both early detection and adequate treatment of hyperglycaemia is important. For both purposes the measurement of urinary glucose, blood glucose and glycated proteins has been proposed. However, it has been demonstrated that the measurement of glucose in the urine provides unreliable information about the glycaemic status (Service et al., 1972) and its value as a screening test is also limited (Lind and Hytten, 1972).

The measurement of the blood glucose concentration is commonly used for screening and diagnostic purposes. The information obtained provides a reliable estimate of the actual glycaemic state at the time of blood sampling. Measurements performed in the fasting individual or obtained at random can be used to screen for diabetes mellitus, whereas the outcome of the OGTT is principally used to confirm the diagnosis. However, one should keep in mind that the moderate reproducibility of the OGTT limits its diagnostic value (O’Sullivan and Mahan, 1966; Siperstein, 751975; Kobberling et al., 1980). Besides, the OGTT is expensive and time-consuming and unpleasant to the patient, who may experience nausea, vomiting, abdominal bloating, and even headache.

With the detection of haemoglobin A1c (HbA1c), a non-enzymatically glycated derivative of haemoglobin, a method became available for evaluating the quality of long-term glycaemic control. HbA1c is identical in structure to the major component haemoglobin A, except that glucose is attached to the NH2-terminus of the
β-chain. Nowadays the measurement of HbA₁c is widely accepted as a quantitative index of the average blood glucose concentration over the preceding 6-10 weeks (Koenig et al., 1976; Gonen et al., 1977; Gabbay et al., 1977; Bunn et al., 1978). On the other hand, the value of HbA₁c to screen a population for diabetes mellitus and/or gestational diabetes is still disputed (Lester et al., 1985; Cousins et al., 1984; Morris et al., 1986). Most laboratory techniques for measuring HbA₁c are hampered by the fact that they have shortcomings in the measurement procedure, which may be time-consuming, laborious, expensive, or unsuitable for routine purposes in a clinical laboratory setting.

It has become clear that non-enzymatic glycation is not unique for haemoglobin. In fact, this phenomenon is a common post-translational reaction of all proteins in vivo and in vitro. Next to haemoglobin, non-enzymatic glycation has been observed in serum proteins and in a large number of other body proteins such as eye lens crystallins (Stevens et al., 1978), collagen (Kohn and Schneider, 1982), peripheral nerve proteins (Vlassara et al., 1981), and glomerular basement membrane (Sasser and Poffenbarger, 1983). As non-enzymatic glycation increases as a function of the blood glucose concentration, it has often been speculated that this phenomenon plays an important role in the pathogenesis of chronic complications of diabetes mellitus (Brownlee et al., 1984, 1988; Raskin and Rosenstock, 1986).

The observation that also the glycation of serum albumin and other serum proteins is accelerated in poorly controlled diabetics, led to the introduction of glycated serum protein (GSP) measurement as a new diagnostic tool for glycaemic control (McFarland et al., 1979; Dolhofer and Wieland, 1979, 1980; Yue et al., 1980). GSPs differ from HbA₁c in that they reflect glycaemia over a shorter period, i.e. 1-3 weeks (Dolhofer and Wieland, 1980; Hindle et al., 1986; Baker et al., 1984). Therefore, the GSP concentration forms an index of intermediate-term glycaemic control. A number of methods have been developed to quantitate GSPs. Most of these are laborious, time-consuming, and expensive as is the measurement of HbA₁c. However, in 1982, Johnson and co-workers described a new colorimetric assay for the measurement of the GSP concentration. This so-called 'fructosamine test', has the advantage of technical simplicity, low cost, and ease of automation using standard laboratory equipment. Therefore, the fructosamine test is the method of choice for measurement of the GSP concentration.

Aim of this study

The present study was designed to evaluate the possibilities and limitations of fructosamine measurement:
1. as a screening test to identify patients with impaired glucose tolerance, diabetes mellitus, or gestational diabetes,
2. as a diagnostic test for glycaemic control in diabetics,
3. as a test during pregnancy for the prediction of hyperglycaemia-related adverse neonatal outcome and large-for-gestational-age (LGA) births.

If appropriate, fructosamine data will be compared with HbA1 values. The results of the study will be preceded by an extensive review of the literature on non-enzymatic glycation of proteins.

Chapter 2

Non-enzymatic glycation of proteins; a review

Protein-sugar compounds

Linkage of a sugar to a protein can be achieved either by enzymatic or non-enzymatic reactions. Because of improper use of the terms glycation, glycosylation and glucosylation in the literature, the IUPAC-IUB Joint Commission on Biochemical Nomenclature decided to define the term ‘glycation’ as any reaction that links a sugar to a protein, whether catalyzed by an enzyme or not (Roth, 1983). An example of enzymatic coupling of glucose to proteins is seen in the synthesis of biologically important glycoproteins such as fibrinogen and haptoglobin, in which molecules glucose is linked at a specific site. On the other hand, in the non-enzymatic process, glucose may react with several NH₂-groups along any available peptide chain. The non-enzymatic process often has an adverse effect on the structure and thus on the function of the protein. For example, lens crystallins may change through non-enzymatic glycation, resulting in cataract.

2.1 The glycation reaction

In 1912 Maillard, a food chemist, was the first to describe the non-enzymatic reaction between glucose and protein. This so-called ‘Maillard reaction’ is responsible for the browning phenomenon that occurs when milk and other foods are heated; the non-enzymatic reaction between glucose and proteins results in poorly soluble brown products. Until recently, only few biologists recognized that the same reaction is likely to take place in vivo as well, particularly in long-lived proteins (Monnier et al., 1984).

Early glycation products

The glycation starts with the formation of a Schiff’s base by the reaction of the active hydroxyl group of an aldohexose with an available free primary amino group in the protein molecule. The ε-NH₂ groups in lysine moieties are often involved in this reaction, leading to formation of relatively unstable Schiff’s bases. The kinetics and equilibrium constants of the latter have been studied for human serum albumin (Baynes et al., 1984) and haemoglobin (Higgins and Bunn, 1981) and a remarkable similarity was found. The equilibrium constants were proportional to both the rela-
tive lysine content and glucose concentration. Steady-state concentrations of Schifl's base are reached within hours.

The formation of the relatively unstable Schiff's base is followed by its decomposition through Amadori rearrangement, giving rise to the formation of the more stable Amadori-type product. The primary 1-imino-1-deoxy-glucose derivative is transformed into a more stable 1-amino-1-deoxy-fructose group which is covalently bound to the protein molecule. The formation of the latter complex has led to the expression 'fructosamines' (figure 2.1).

![Chemical diagram]

*Figure 2.1* Ketoamine formation

Although the kinetics and equilibrium constants for the formation of Schiff's base are similar for albumin and haemoglobin, the rate of formation of the Amadori products is about 4.5 times more rapid for human serum albumin than for haemoglobin (Higgins and Bunn, 1981; Baynes et al., 1984). Therefore, in response to a prolonged elevation in blood glucose, the increase in glycated albumin will precede that in glycated haemoglobin.

Both the Schiff's base formation and the Amadori rearrangement are reversible equilibrium reactions. It follows that the formation of these so-called 'early glycation products' reaches a steady-state plateau within a given period of time. The concentration of the early glycation products increases when blood glucose concentrations are high, but returns to normal when blood glucose levels normalize. The early glycation products do not accumulate.

*Advanced glycation end products*

Some of the Amadori products on proteins with long half-lives such as lens crystallins, collagen, elastin and myelin do not easily dissociate. Instead, they undergo a further series of slow, complex, irreversible chemical rearrangements and dehydra-
tions, resulting in formation of so-called 'advanced glycation end products' (Brownlee et al., 1984(a); Cerami et al., 1987). These products can be identified qualitatively by their characteristic brown pigment and fluorescence. The irreversibility of the chemical reaction that leads to the formation of advanced glycation end products implies that the concentration of the latter does not return to normal when hyperglycaemia is corrected. Instead, the products accumulate over the lifetime of proteins, such as for instance on collagen. The rate of this accumulation is proportional to the average blood glucose concentration over an extended period.

In non-diabetics, a linear increase with age in the amount of advanced glycation end products has been demonstrated in dura collagen. In diabetics, these products have been found to accumulate to a larger extent than in non-diabetics (Monnier et al., 1984). In addition, a strong correlation has been reported between accumulated levels of advanced glycation end products in collagen and the severity of diabetic retinopathy (Monnier et al., 1986).

Later in this chapter the probable role of excessive accumulation of advanced glycated end products on biologically important proteins in the pathogenesis of various diabetic complications will be discussed in more detail.

2.2 Non-enzymatic glycation of haemoglobin

2.2.1 History

Already in 1958 it was demonstrated that 3 minor components could be discerned in human haemoglobin: HbA1a, HbA1b, and HbA1c (Allen et al., 1958). About 10 years later it was demonstrated that the concentration of one of these components, HbA1c, was about 2-3 times higher in diabetics than in non-diabetic controls (Rabbar et al., 1969; Trivelli et al., 1971). Bunn and co-workers (1976) reported that the cause of the increased HbA1c concentration in diabetics was related to abnormal carbohydrate metabolism. The latter workers demonstrated that HbA1c was formed by a post-translational reaction between glucose and haemoglobin A. They also presented evidence that glucose was attached to the N-terminal amino group of the β-chain of haemoglobin A.

Also HbA1a and HbA1b are post-translational modifications of HbA (Bunn et al., 1976). HbA1a and HbA1b differ from HbA in that either fructose-1-6-phosphate or glucose-6-phosphate is attached to the NH₂-terminus of the β-chain (HbA1a), or the compound is a deamination product of HbA (HbA1b) (table 2.1).

In 1976, Koenig and co-workers made mention of the relation between HbA, and blood glucose in diabetics. They demonstrated that HbA, correlated positively with both the daily average blood glucose concentration and the daily urinary glucose loss. The HbA, concentration was found to correlate better with the mean blood glucose concentration over the preceding 1-3 months than with the actual glu-

cose level at a single point in time. The authors also noted that accurate metabolic control in diabetics reduced the HbA₁ fraction.

Nowadays the measurement of HbA₁ in diabetics is widely accepted as an objective and quantitative tool for assessing the time-averaged blood glucose concentration and thus the quality of treatment over the preceding 6-10 weeks (Koenig et al., 1976; Goten et al., 1977; Gabbay et al., 1977; Buma et al., 1978).

One of the major controversies among specialists in diabetes mellitus has been the relation between the accuracy of blood glucose control and the risk of developing long-term complications of diabetes mellitus. Although it is obvious to assume that maintenance of normoglycaemia in diabetics ought to diminish the risk of secondary complications, it has been difficult to obtain conclusive evidence. A reason for the latter may be the lack of adequate means of measuring the accuracy of glycaemic control. Nevertheless, some recent prospective studies have provided evidence that the occurrence of long-term diabetic complications is closely correlated with the quality of glycaemic control based upon the HbA₁ value (Holman et al., 1983; Raskin et al., 1983; The Kroc collaborative study group, 1985; Dahl-Jorgensen et al., 1986).
2.2.2 Methods for quantitation of glycated haemoglobin

For the determination of the glycated haemoglobin derivatives, especially HbA1c, various chromatographic, electrophoretic, immunochemical, and photometric methods have been developed. Recently, these methods have been reviewed by Miedema and Casparie (1984).

The development of a whole variety of quantitative methods not only underlines the interest in HbA1c, it also demonstrates the lack of superiority of one single method. A major problem of most methods is that they are time-consuming, laborious, and expensive. Some methods are unsuitable for routine use in a clinical chemistry laboratory because automation is not possible. In other methods the presence of Schiff's base or free glucose influences the final result. Differences in methodology and reference values also complicate the comparison of studies on HbA1c.

None of the measurement techniques for HbA1c is clearly superior. Usually HbA1c is isolated by either electrophoresis or column chromatography, followed by quantitative photometric measurement.

2.2.3 Effect of glycation on the haemoglobin function

In HbA1c glucose is covalently bound to the N-terminal valine group of the β-chain. This site is normally involved in the binding of organic phosphates. 2,3-diphosphoglycerate (2,3-DPG) is an important regulator of intracellular haemoglobin function. Binding of 2,3-DPG to haemoglobin reduces the affinity of haemoglobin for oxygen. Blockage of the N-terminal site of haemoglobin by glycation interferes with the binding of 2,3-DPG. This action leads to a higher oxygen affinity of HbA1c as compared to that of HbA0 (Bunn and Briehl, 1970). In compensation, the concentration of 2,3-DPG in the erythrocytes is increased in diabetics, resulting in a decreased affinity of non-glycated haemoglobin (HbA0) for oxygen (Ditzel et al., 1975). It is unlikely that the marginal abnormality of the oxygen dissociation curve in diabetics interferes with tissue oxygen transport, as suggested by the small effect on tissue oxygenation observed in patients with mutant haemoglobins, in whom much greater shifts in the oxygen dissociation curve have been demonstrated (Bunn et al., 1978).

2.2.4 Clinical applications of the measurement of glycated haemoglobin

The first data on HbA1c concentrations in diabetic patients were reported in the early seventies (Trivelli et al., 1971) and a 3-fold higher concentration of HbA1c was found in diabetics as compared to a non-diabetic reference group. In 1976, Koenig and co-workers studied the effects of quality of glycaemic control on the levels of HbA1c in diabetic patients. During optimal glycaemic control, the HbA1c con-
concentration was clearly lower than in conditions of poor control. Leslie and associates (1978) reported that 3 of 5 diabetics with an elevated HbA1 concentration in pregnancy gave birth to children with fatal congenital anomalies, whereas no abnormalities were noted in 20 children born to diabetic mothers with normal HbA1 concentrations during pregnancy. The measurement of HbA1 concentration has also been suggested as an alternative to the oral glucose tolerance test for detection of diabetes mellitus (Dods and Bolney, 1979). These and other results initiated a series of studies to evaluate the clinical usefulness of HbA1 measurements for screening and diagnostic purposes.

2.2.4.1 Glycated haemoglobin and glycaemic control

Since the mid-seventies, measurement of HbA1 has been proposed as an index of diabetic control. For this reason the relation between the HbA1 concentration and a number of other commonly used parameters of diabetic control will be discussed.

Glycated haemoglobin and glucosuria

The daily urinary glucose loss has been used as an approximation of blood glucose control. This variable correlated with the HbA1 concentration determined 2 months later in insulin-dependent juvenile diabetics (Gabbay et al., 1977; Dunn et al., 1979).

Glycated haemoglobin and the 'clinical impression' of glycaemic control

The 'clinical impression' of the quality of glycaemic control was also found to correlate with the concentration of HbA1 (Gonen et al., 1977). However, the lack of firm criteria for classifying clinically the quality of metabolic control in the latter study, as well as the inability to confirm these findings in a subsequent study using a well-defined scoring system (Van Heyningen et al., 1986), raises some doubts about the reported correlation.

Glycated haemoglobin and the fasting blood glucose concentration

It has been suggested that the fasting blood glucose concentration could serve as a reliable index of glycaemic control in patients with non-insulin-dependent diabetes mellitus (NIDDM). Holman and Turner (1979) demonstrated that the pattern in overnight plasma glucose concentrations in lean, diet-treated subjects with NIDDM varied little with time. In addition, they showed that the fasting blood glucose concentration in these patients after an overnight fast correlated closely with diurnal plasma glucose values. Therefore, this so-called 'basal glucose level' was said to provide a convenient estimate of the quality of glucose control in NIDDM (Holman and Turner, 1980).

By comparing the value of HbA1 with that of the fasting blood glucose in the qual-
ity assessment of glycaemic control, a difference was found between NIDDM and IDDM patients. In NIDDM patients the HbA₁c concentration was found to be as reliable as the fasting blood glucose concentration, whereas in IDDM patients the concentration of HbA₁c was superior to the fasting blood glucose concentration (Pecoraro et al., 1986; Mosca et al., 1987). The difference is likely to be a result of less stable blood glucose concentrations in IDDM than in NIDDM patients. This instability has a greater impact on the fasting blood glucose concentration than on the HbA₁c concentration.

*Glycated haemoglobin and the mean blood glucose concentration*

The repeated measurement of blood glucose concentration over one day is a method frequently employed for evaluating glycaemic control in diabetics. A majority of patients with diabetes mellitus measure their own blood glucose concentrations at home by fingerprick and subsequently adjust their insulin dose. This approach has led to a better overall metabolic control. In more or less stable home-controlled IDDM patients, HbA₁c was found to correlate well with the mean blood glucose concentration during each of the three preceding months (Paisey et al., 1980). It should be stressed that patient compliance is a prerequisite for obtaining such results in this type of management of diabetes. In fact, discrepancies between home-measured and hospital-measured blood glucose concentrations do occur and could reflect inadequate patient compliance (Miedema, 1981; Langer and Mazze, 1986). As nowadays home glucose monitoring is a well-accepted way of achieving diabetic control, insight into patient compliance has become important. Occasional HbA₁c measurement may provide a satisfactory check on patients’ reliability (Miedema and Casparie, 1984).

Although there is general agreement about the fact that a normal HbA₁c concentration in diabetics indicates adequate blood glucose control during the preceding 6-8 weeks, one should keep in mind that HbA₁c has limited value for the monitoring of short-term changes in glycaemic control. This limitation is due to the kinetic properties of HbA₁c, with respect to formation and disappearance. The long half-life of HbA₁c (60 to 90 days) implies that it takes several weeks before an improvement in glucose control will be reflected in a lower concentration of HbA₁c. On the other hand, since the rate of HbA₁c formation exceeds that of its clearance (Higgins and Bunn, 1981), recurrent brief periods of hyperglycaemia may increase the concentration of HbA₁c disproportionately. It follows that an elevated concentration of HbA₁c does not necessarily reflect continuous poor glycaemic control, but may also be the result of brief periods of poor glycaemic control in the preceding weeks. Inasmuch as glucose control is more stable in NIDDM than in IDDM, measurement of HbA₁c in the former group correlates better to other parameters of glucose control than in the latter group.
2.2.4.2 Glycated haemoglobin measurement as a screening test for impaired glucose tolerance and diabetes mellitus

The relationship between HbA1 and the glycaemic state has led various investigators to evaluate the possibilities of HbA1 measurement as a screen for diabetes mellitus in an entire population. Comparison of earlier studies on the relation between HbA1 and OGTT is hampered by the lack of standardization in performance and classification of the OGTT. However, the increasing acceptance of WHO recommendations on this matter has improved the comparability of more recent studies.

Lester and co-workers (1985) compared the results of the OGTT (WHO criteria) and the HbA1 concentration in 168 subjects suspected of diabetes mellitus. The value of HbA1 for screening purposes was determined from their data by calculating the sensitivity, specificity, and positive and negative predictive values (table 2.2 and table 2.3). The sensitivity and specificity of the HbA1 concentration for identifying patients with diabetes mellitus were good (96% and 97% respectively).

Sensitivity = \( \frac{TP}{TP + FN} \) x 100%

Specificity = \( \frac{TN}{TN + FP} \) x 100%

Positive predictive value = \( \frac{TP}{TP + FP} \) x 100%

Negative predictive value = \( \frac{TN}{TN + FN} \) x 100%

Prevalence = \( \frac{TP + FN}{TP + FN + FP + TN} \) x 100%

Recently, Little and co-workers (1988) evaluated the value of HbA1 as a screening test for diabetes mellitus in 381 Pima Indians. An OGTT on the base of WHO standards was performed in all subjects. Table 2.3 shows that the results differed from the results of Lester and co-workers (1985) as well as from our own results (Salemans et al., 1987). The differences between the sensitivity and specificity may be
the result of different, arbitrarily chosen, cut-off values (upper limit of normal range) and of a different incidence and/or degree of abnormal glucose tolerance in the population studied. Optimal cut-off values can be obtained by constructing a receiver operating characteristic curve (ROC). This curve is a graphical presentation of sensitivity plotted against specificity for different cut-off values. In chapter 5 we will report on this method and its application for assessment of the cut-off value of HbA₁ in screening for diabetes mellitus.

- The upper limit of a normal HbA₁ concentration was defined as 2 SD above the mean of the reference population.
- The OGTTs were performed and classified according to WHO criteria (1985).
- PV: predictive value.
- HPLC: high pressure liquid chromatography.

From the results of several studies (as listed in table 2.3) it can be concluded that the HbA₁ measurement has little value when used to detect IGT, whereas its value for detecting DM is better, but also not conclusive.

It is not surprising that IGT can not be detected by HbA₁ measurement since the two parameters measure quite different aspects of glucose metabolism. An abnormal OGTT, especially IGT, reflects a temporary elevation of the blood glucose concentration after a non-physiological glucose load. These patients may be normoglycaemic on their own dietary regimen and therefore the HbA₁ concentration may remain within the normal range. Moreover, one should keep in mind that the OGTT may also be occasionally abnormal due to transient conditions such as medication, illness or stress. Because of the latter and many other factors, the OGTT has a moderate reproducibility (O'Sullivan and Mahan, 1966; Siperstein, 1975;
Kobberling et al., 1980; Cummings and Fraser, 1988). It is concluded that HbA<sub>1</sub> measurement is an imperfect method for identifying IGT or DM. The most important reason to identify diabetics as early as possible is to start early with treatment, thus diminishing the risk of long-term sequelae (Brownlee et al., 1984a, 1988; Raskin and Rosenstock, 1986). Only hyperglycaemic patients need treatment, irrespective of the outcome of an OGTT. The fact that a patient with an elevated HbA<sub>1</sub> concentration will generally be hyperglycaemic and a patient with an abnormal OGTT may be normoglycaemic, suggests that measurement of HbA<sub>1</sub> may be more appropriate than the OGTT for selecting the target population.

2.2.4.3 Glycated haemoglobin and pregnancy

Measurement of HbA<sub>1</sub> may be useful in several conditions during pregnancy. The HbA<sub>1</sub> concentration has been recommended for use in screening for gestational diabetes and for identifying patients with hyperglycaemia-related increased risk of major congenital anomalies, macrosomia, perinatal morbidity and perinatal mortality.

Glycated haemoglobin in normal pregnancy

In order to evaluate the usefulness of HbA<sub>1</sub> measurement during pregnancy it is necessary to be informed about the normal pattern throughout pregnancy. The pattern of the HbA<sub>1</sub> concentration in pregnancy has been studied cross-sectionally (Lind and Cheyne, 1979; Phelps et al., 1983) and longitudinally (Hanson et al., 1983; Worth et al., 1985; Griffiths et al., 1987). The results of these studies indicate that the HbA<sub>1</sub> concentration decreases slightly in the first half of pregnancy, to reach its lowest value between 17 and 24 weeks. Towards term, the HbA<sub>1</sub> concentration has been reported either to remain low (Lind and Cheyne, 1979; Hanson et al., 1983) or to increase again gradually (Phelps et al., 1983). Our own data on this subject will be presented in chapter 6.

The slight decrease of the HbA<sub>1</sub> concentration in the first half of pregnancy, reported in most studies, may be related to a small reduction in the mean blood glucose concentration during normal early pregnancy (Lind et al., 1973; Gillmer et al., 1975). It may also be related to the increase of the total erythrocyte volume after the 10th week of pregnancy (Hyttten and Lind, 1973). The rise in red cell volume in early pregnancy is associated with a rise in the proportion of young cells. These young cells contain less HbA<sub>1</sub> than the older cells because of shorter exposure time to glycation. Because of this phenomenon the HbA<sub>1</sub> concentration may also decrease.

The observations on the trend of the HbA<sub>1</sub> concentration in the second half of pregnancy are less uniform. Nevertheless, it seems that the HbA<sub>1</sub> concentration changes together with the fasting blood glucose concentration. The differences in the HbA<sub>1</sub> pattern in late pregnancy are probably related to the fact that different
populations have been investigated, as indicated by the concomitant differences in fasting glucose concentrations.

**Glycated haemoglobin as a screening test for gestational diabetes**

It is generally accepted that early identification and treatment of gestational diabetes is important for preventing the development of the well-known complications, particularly macrosomia (Gabbe et al., 1977(a); Coustan and Imanrah, 1984; Widness et al., 1985). The lack of agreement about which screening procedure should be employed led to a number of studies to determine the screening value of HbA₁ with respect to gestational diabetes. In several studies the ability of HbA₁ to identify the gestational diabetics, defined according to O'Sullivan's criteria, was found to be disappointing, as indicated by a low sensitivity and specificity (Cousins et al., 1984; Artal et al., 1984). To our knowledge, in only one study (Morris et al., 1986(a)) were these particular patients indeed identified satisfactorily on the basis of an elevated HbA₁ concentration between the 10th and 15th weeks of gestation. However, in this study the authors did not evaluate a general population but a population selected on the base of an abnormal OGTT. The results of a study from our group (Salesmans et al., 1987; chapter 5) are in agreement with those reported by most investigators on this matter, namely that HbA₁, routinely measured in a pregnant population is an inadequate screening test for gestational diabetes.

**Glycated haemoglobin and congenital anomalies**

The incidence of spinal anomalies (including the caudal regression syndrome), situs viscerum inversus, skeletal malformations, pseudohermaphroditism, urological anomalies, and heart anomalies has been found to be significantly higher in foetuses of diabetics than in those of a reference non-diabetic population (Kucera, 1971; Chung and Myrianthropoulos, 1975; Milunsky et al., 1982).

Developmental morphological dating shows that the malformations which occur more frequently in the offspring of diabetic women are related to a developmental disturbance which occurs before the seventh week of gestation (Mills et al., 1979). Although the pathogenetic mechanisms responsible for the high incidence of congenital anomalies among the infants of diabetic mothers are still poorly understood at this moment, there is growing evidence that poor glycaemic control in early pregnancy plays a crucial role in this respect. This does not exclude the contribution of hereditary factors to diabetic teratogenesis. In rat experiments, congenital anomalies were found to result from a teratogenic insult in a genetically predisposed organism (Eriksson, 1986). The relation between the higher incidence of spontaneous abortion in patients with an elevated HbA₁ concentration during early pregnancy, provides additional support for the concept that poor glycaemic control is associated with a teratogenic effect (Key et al., 1987).

Leslie and associates (1978) observed in a small population sample that the early-pregnancy HbA₁ concentrations had been elevated in diabetic women giving birth
to babies with congenital anomalies. These observations have been confirmed in various studies (Miller et al., 1981; Fuhrmann, 1984; Key et al., 1987; Lips, 1988(a)), the results of which suggest that the incidence of malformations is proportional to the degree of elevation in HbA1 level during the first trimester of pregnancy (table 2.4).

* Major and minor malformations
** Major malformations
The data stress the importance of meticulous control of the glycaemic state in diabetics already before conception in order to minimize the risk of congenital malformation and/or spontaneous abortion. In the first trimester of diabetic pregnancy, the measurement of HbA1 seems to provide information both on the average glucose level during the period of organogenesis and on the risk of malformation of the foetus.

_Glycated haemoglobin and birth weight_

Foetal macrosomia is a well-known feature of diabetic pregnancy (Gabbe et al., 1977 (b); Kitzmiller et al., 1978; Lips, 1988(b)). Pedersen (1977) and later Abell (1979) and Widness and co-workers (1978) suggested that maternal hyperglycaemia leads to foetal hyperglycaemia which, in turn, affects intra-uterine growth and development. While several authors have laid emphasis on the description of the relationship between maternal hyperglycaemia and foetal macrosomia, others described the effect of rigid glucose control in diabetic pregnancy on birth weight (Gyves et al., 1977; Landon et al., 1987). However, since rigid maternal glucose control during diabetic pregnancy does not always prevent macrosomia, factors other than those in glucose handling may contribute to the development of foetal macrosomia (Kalkhof, 1985; Moore et al., 1987).

The relation between the quality of maternal glycaemic control and foetal growth led several investigators to study the relation between the HbA1 concentration and the infant’s birth weight. Hanson and associates (1983) were unable to find a correlation in 19 non-diabetic pregnant women between the first trimester HbA1 concentration and relative birth weight (i.e. actual birth weight in percent of the anticipated 50th percentile weight, adapted for gestational age and sex). In contrast, Morris and associates (1985(a)) reported a higher incidence of large-for-gestational-age (LGA) infants in both non-diabetic and diabetic women when the HbA1 level in the first trimester of pregnancy had exceeded 7%. In both pregnant diabetics and gestational diabetics, the third trimester HbA1 concentrations (Widness et al., 1978) and the HbA1 concentrations during labour (Fadel et al., 1986) were also found to correlate with birth weight. Such a relation was not found in a control group of women with normal glucose tolerance during pregnancy (Fadel et al., 1986; Bacigalupo et al., 1984).

In summary, in diabetics neonatal macrosomia seems to occur more often when the HbA1 concentration has been elevated during the preceding pregnancy.

2.3 Non-enzymatic glycation of serum proteins

2.3.1 History

Non-enzymatic glycation has been shown to occur in a large number of proteins including serum proteins. Glycation of albumin had already been observed in the
horse in 1956 (Michiel and Klemer, 1956), but not until the mid-seventies was its clinical importance recognized. In 1979, glycated rat and human albumin were prepared in-vitro, whereas the natural occurrence of glycated albumin was demonstrated for the human (Dolhofer and Wieland, 1979; Day et al., 1979). In the same period it was demonstrated that glycation of serum proteins was increased in diabetics (McFarland et al., 1979). In the latter study it was also demonstrated that the fractional glycation of albumin correlated closely with that of total serum proteins and that the concentration of these glycated proteins varied as a function of the fasting glucose concentration. Dolhofer and Wieland (1980) provided evidence that the level of glycated albumin was dependent upon the blood glucose concentration. The recognition of the potential clinical importance of the GSP measurement in the management of diabetes mellitus (Kennedy et al., 1981) and the introduction of a simple method for its measurement (Johnson et al., 1982) aroused interest in the determination of GSP in various clinical conditions.

2.3.2 Methods for quantitation of glycated serum proteins

Many different methods, recently reviewed by Armbruster (1987), have been developed to quantitate non-enzymatic GSPs. A major disadvantage of the phenylhydrazine procedure (Ghiggeri et al., 1986) for use in a clinical chemistry laboratory is the interference of Schiff's base with the assay. The furosine procedure (Schleicher and Wieland, 1981; Schleicher et al., 1984) is claimed to be rapid, specific, sensitive and precise. However, the required 18-hours hydrolysis step is a major drawback for routine use in the laboratory. The measurement of GSPs by affinity chromatography (Brownlee et al., 1980; Yatscoff et al., 1984) is not widely used in the clinical laboratory. Routine use of this relatively simple method is obstructed by the time-consuming assay involved with little chance of automation. The thiobarbituric acid colorimetric procedure is precise and semi-automated (Moore et al., 1986), but analysis time and the number of steps make it cumbersome. In 1982 a new colorimetric assay was introduced for measurement of GSPs. This so-called 'Fructosamine test' is simple, cheap and automated (Johnson et al., 1982). Because of its precision and ease of performance, this method is now generally used for the measurement of GSPs in the clinical chemistry laboratory. In chapter 3 various aspects of this test will be discussed.

2.3.3 Effect of glycation on function and metabolism of serum albumin

The human serum proteinas are continuously modified by glycation but this phenomenon occurs at a higher rate in diabetics than in non-diabetics. Also albumin, which is the most abundant protein in human serum, is subject to non-enzymatic glycation. Inherent in non-enzymatic glycation of a protein is often a
change in its chemical, physical and biological properties. Using a fluorescence technique, Shaktai and co-workers (1984) demonstrated that non-enzymatic glycation of human albumin leads to a change in the configuration of the molecule. Glycation of albumin has been associated with a change in its affinity for drugs and for bilirubin. In vitro, it has been demonstrated that salicylate (Mereish et al., 1982) and bilirubin (Shaktai et al., 1984) binding is reduced in glycated albumin when compared to non-glycated albumin. However, this phenomenon appears to have little clinical impact since, in vivo, this effect has not yet been observed at the highest possible degree of glycation.

Glycation of proteins may also lead to an increased clearance rate of these proteins. However, data on the half-life of glycated albumin are conflicting and to our knowledge have only been obtained in laboratory animals. In rats, the half-life of glycated albumin was similar to that of non-glycated albumin (Day et al., 1979), whereas in dogs the half-life of glycated albumin was lower than that of non-glycated albumin (Morris and Predy, 1986(b)). In animal studies several biological properties of albumin are found to be affected by glycation. However, for the time being, we do not have any evidence that in humans (even in poorly controlled diabetes) non-enzymatic glycation of albumin interferes with its normal physiological function.

2.3.4 Interferences in the measurement of glycated serum proteins

Variables other than glucose may interfere with the measurement of GSPs. Several of these factors will be discussed in this paragraph.

2.3.4.1 Effect of protein concentration and protein composition on the measurement of glycated serum proteins

Several authors studied the effect of variations in albumin and total protein concentration on the fructosamine concentration. Under normal conditions, fructosamine varied independently of both the albumin and the total protein concentrations. However, in patients with uncompensated nephrotic syndrome, in whom serum albumin concentrations had decreased to below 30 g/l, the fructosamine concentrations were significantly lower than in normal subjects (Baker et al., 1983). Similar results have been reported in more recent studies (Lloyd and Marples, 1984; Hindle et al., 1985; Howey et al., 1987). Our own results on this subject will be presented in chapter 3. There is general agreement that correction of fructosamine is not needed when the albumin concentration exceeds 30 g/l since the magnitude of the correction would be smaller than the intra-assay error of both the fructosamine and the protein measurements.
Glycation of various serum proteins has been studied ever since the discovery of increased levels of glycated serum albumin in diabetics. It has become evident that, besides albumin, other serum proteins are also subject to non-enzymatic glycation. Incubation of freshly prepared serum with radioactive glucose resulted in binding of radioactivity not only to albumin but also to other serum proteins (Dolhofer and Wieland, 1979; Schleicher et al., 1984; Mosca et al., 1987). Per gram of protein, radioactivity was highest in the albumin and \( \alpha_1 \)-globulin fraction, followed by the \( \gamma \)-globulin fraction. Approximately 78% of the serum-protein-bound radioactivity was recovered from the albumin fraction. On a molecular base, Mosca and co-workers (1987) observed the following fractional glycation for each protein: albumin 100%, total immunoglobulins 76.2%, transferrin 38.1% and \( \alpha_2 \)-macroglobulin 14.3%.

It can be concluded that many GSPs contribute to the total amount of ketoamine linkages. Glycated albumin contributes most to the total GSP concentration because of its large fractional contribution to the serum proteins. Moreover, albumin may comprise more ketoamine linkages per molecule than other much larger serum protein molecules. Therefore, a change in the albumin concentration may influence the GSP concentration, whereas increases or decreases in the concentrations of other serum proteins have little effect on the GSP concentration.

2.3.4.2 The influence of protein half-life on the concentration of glycated serum proteins

Proteins with short half-lives are generally less glycated than those with long half-lives, due to shorter exposure to glucose. In patients with a normal protein metabolism, the influence of protein half-lives on the GSP concentration is constant unless serum protein turnover changes. For example, in thyrotoxic patients with accelerated protein turnover, the GSP concentration was lower than in euthyroid controls, whereas the opposite effect was observed in hypothyroid patients (Lloyd and Marples, 1986). Since the protein and glucose concentrations in these groups were comparable, these changes are likely to be related to differences in protein turnover. From the above it is concluded that GSP levels in patients with an abnormal serum protein turnover should be interpreted with caution.

2.3.4.3 Influence of age and sex on the concentration of glycated serum proteins

Introduction of the GSP measurement for screening and diagnostic purposes should be preceded by an evaluation of the effect of age and sex on the concentration of GSP. Sex-dependency could not be demonstrated either in 111 children aged between one and eighteen years (Krause et al., 1987) or in 145 non-diabetic adults (Lim and Staley, 1985).
There are conflicting data concerning the relationship between the GSP concentration and age, with some investigators reporting similar values in children and in adults (Allgrove and Cockrill, 1983), whereas others have observed lower values in children (Hindle et al., 1986; Krause et al., 1987). In a study in 3664 non-pregnant volunteers, the GSP concentration was found to increase gradually during the first fifteen years of life (Roberts and Baker, 1986). There was no further change between twenty and and fifty years (figure 2.2). The lower GSP concentration in children can be caused by their higher protein turnover rate (James, 1978).

Figure 2.2 Relation between serum fructosamine concentration and age in 3664 non-pregnant women. Hatched area is the reference interval (Roberts and Baker, 1986) (with permission)

2.3.5 Clinical applications of glycated serum protein measurements

Chronic hyperglycaemia in diabetics results in a rise in the concentration of non-enzymatically glycated proteins. Because of this feature, HbA1c measurement has gained general acceptance in the management of diabetes. The HbA1c concentration reflects the blood glucose levels during the preceding six to ten weeks and is thus an index of long-term blood glucose control. However, the long survival time of haemoglobin (120 days) implies that a high HbA1c level is likely to persist at least for several weeks after normoglycaemia has been achieved. Since most serum proteins have a much shorter half-life (t½, albumin = 18 days) than haemoglobin, the GSP measurement may provide more reliable information on the recent glycaemic status. This feature may offer the advantage that fairly rapid information can be obtained about, for example, the efficacy of a change in treatment.
2.3.5.1 Glycated serum proteins and glycaemic control

The GSP concentration is higher in diabetics than in non-diabetic controls, with virtually no overlap (Dolhofer and Wieland, 1979 and 1980; McFarland et al., 1979; Kennedy et al., 1981; Johnson et al., 1982). This feature has been the trigger to further analyse the clinical applicability of the relation between the GSP level and the glycaemic status.

**Glycated serum proteins and stable glycaemic control**

In clinical practice the 'clinical impression' is occasionally used to evaluate the quality of glycaemic control. In general, this 'clinical impression' is vague and subjective, due to the versatility of symptoms and laboratory tests on which it is based. Therefore, the good correlation reported between the fructosamine concentration and the 'clinical impression score of glycaemic control' (Kutter and Thoma, 1985; Buyssehaert et al., 1986) should be interpreted with caution.

The fasting blood glucose concentration is frequently used to evaluate the quality of glycaemic control in diabetics (Holman and Turner, 1979 and 1980). It is generally agreed that the GSP concentration and the fasting blood glucose concentration are correlated (Johnson et al., 1982; Jones et al., 1983; Nelson et al., 1985; Baker et al., 1983; Kutter and Thoma, 1985; Koskinen et al., 1987; Poli et al., 1987; Jernstorpe et al., 1988). This correlation is closer in NIDDM than in IDDM (Kennedy et al., 1981; Mosca et al., 1987), most probably due to the less stable glycaemic state in IDDM.

The glucose concentration 2 hours after a meal provides additional information about the quality of glycaemic control in diabetics. Also this parameter was found to correlate with the GSP concentration. Again, the correlation in NIDDM patients was better than in IDDM patients (Smart et al., 1988). Our own results with respect to this relation will be presented in chapter 4.

Glycaemic control can also be evaluated on the base of the average glucose concentration calculated from multiple blood glucose measurements throughout the day. This estimate, determined once weekly for a period of 4 weeks, was found to correlate well with the GSP concentration in a group of stable IDDM patients (Schleicher et al., 1984). Furthermore, a good correlation was found in pregnant diabetics between the GSP concentration and the average glucose concentration calculated from multiple postprandial glucose measurements determined in the previous week (Morris et al., 1985 (a)).

The correlations between various currently employed estimates of glycaemic status and fructosamine are summarized in table 4.4. From this table it can be concluded that, particularly in stable diabetics, the GSP (fructosamine) concentration appears to provide reliable information on the quality of glycaemic control over a period of 1-3 weeks.
**Glycated serum proteins and deterioration of glycaemic control**

When the blood glucose concentration rises gradually, the rate of formation of ketoamines exceeds the rate of their dissociation and clearance until a new equilibrium level has been attained. This phenomenon results in a higher GSP concentration. In diabetic rats discontinuation of insulin administration led to a new steady-state concentration of GSPs after 4-5 days (Day et al., 1979, 1980). To determine the clinical usefulness of fructosamine measurement in detecting loss of glycaemic control, the effect of discontinuing oral hypoglycaemic medication on the fructosamine concentration was studied in 7 NIDDM patients (Baker et al., 1984). There was a consistent increase in the fructosamine concentration during the first week after drug withdrawal, and a plateau was reached after 1-2 weeks. In rats, steady-state GSP concentrations are reached within a shorter period than in humans, probably due to the short half-life of rat albumin (2 days) relative to that of human albumin (18 days). The number of reports on the effect of deterioration of the normoglycaemic status in the human are limited because of medical and ethical problems associated with such experiments. Nevertheless, there appears to be enough evidence to assume that deterioration of glycaemic control in diabetics will lead to a rapid increase in the GSP concentration. Therefore the GSP concentration is likely to provide useful information for the early detection of deterioration of glycaemic control in diabetics.

**Glycated serum proteins and improvement of glycaemic control**

When a state of poor glycaemic control is adequately treated and normoglycaemia is restored, dissociation and clearance of ketoamines exceed their formation, thus causing a fall in the GSP concentration. Since ketoamines are predominantly composed of glycated serum albumin, the half-life of GSP may theoretically approximate to that of glycated serum albumin, i.e. 18 days. Improvement of the glycaemic status in poorly controlled diabetic patients decreased the GSP concentration by 37% within one week (Kennedy et al., 1981). A fall of the GSP concentration within 3 weeks after improvement in glycaemic status has been confirmed by others (Dolhoffer and Wieland, 1980; Baker et al., 1983; Jones et al., 1983; Cefalu et al., 1988; Krause et al., 1987).

In clinical practice it is often difficult to restore normoglycaemia in diabetics. Particularly in IDDM patients, the glucose concentration may fluctuate over a wide range in spite of an overall reduction in the mean daily blood concentration. In these patients, the accelerated removal of GSPs, associated with the lower mean glucose concentration, is counterbalanced by the enhanced formation of new GSPs during hyperglycaemic episodes. In newly diagnosed diabetics and diabetics with poor glycaemic control, the GSP concentration will only decrease to normal levels when stable normoglycaemia has been reached and few hyperglycaemic episodes occur. The GSP concentration therefore appears to provide valuable information to the clinician for evaluation of overall improvement in the glycaemic status.
2.3.5.2 Glycated serum protein measurement as screening test for impaired glucose tolerance and diabetes mellitus

Screening for IGT and DM can be performed just for epidemiological reasons or to identify (symptom-free) patients in a population. For both purposes it would be convenient to have a simple method at hand with a good sensitivity and specificity which could replace the OGTT. Glycosuria has a poor specificity and sensitivity for DM (Service et al., 1972). Screening for DM by randomly measurin blood glucose during the day fails because of insufficient sensitivity (WHO, 1985). While the value of HbA1 measurement for detection of DM may be adequate, its value for detection of IGT appears to be insufficient (see 2.2.4.2).

Since the GSP concentration gives information on the glycaemic status over a shorter and more recent period, its measurement may be more reliable than the HbA1 concentration as an estimate of actual glucose tolerance. We calculated the sensitivity, specificity, and predictive value of the fructosamine test using data reported by Baker and co-workers (1983) (table 2.5). Although the sensitivity of the test for detection of DM was good, the test was weak with respect to identifying subjects with an IGT. In a larger population we reported comparable results (Salemans et al., 1987). Our data are also listed in table 2.5 but will be discussed in more detail in chapter 5.

Swai and co-workers (1988) reported that fructosamine measurement was a poor screening test for abnormal glucose tolerance. The sensitivity of the fructosamine test for DM was calculated to be only 45% and that for both DM and IGT only 12%. However, their results may be influenced by the high prevalence of IGT and DM in the population studied (33.4%).

Since glucose tolerance tests and average glycaemic ranges (fructosamine) give information on quite different aspects of carbohydrate metabolism, it is not surprising that IGT can not be detected by the measurement of fructosamine. The fructosamine concentration reflects the mean blood glucose concentration during the preceding 1-3 weeks, whereas an IGT test implies a (temporary) abnormal elevation of the blood glucose concentration after a non-physiological glucose load. A subject with an IGT test, may be normoglycaemic under physiological conditions. In these subjects the fructosamine concentration will be normal.

Several stressful conditions such as surgery, trauma and disease may affect carbohydrate metabolism. In these situations it may be difficult to determine whether hyperglycaemia reflects the existence of DM or a temporary stress-related change in the carbohydrate metabolism. In these conditions the GSP concentration (which is less sensitive to acute disturbances in glycaemic control) may contribute to the diagnosis. Kyle and co-workers (1987) have studied the value of serum fructosamine measurement in screening for DM in a coronary care population. In these patients the incidence of hyperglycaemia is high (Oswald et al., 1986) and discrimination between
Table 2.5 Value of fructosamine measurement as screening test for diabetes mellitus (DM) and impaired glucose tolerance (IGT)

- The OGTTs were performed and classified according to World Health Organization (WHO) criteria (1985) or to National Diabetes Data Group (NDDG) criteria (1979).
- PV: predictive value.
- The upper limit of a normal fructosamine concentration was defined as 2 SD above the mean of the reference population.

DM and stress hyperglycaemia is important from a therapeutic and diagnostic point of view (Jaffe et al., 1984). In 107 patients, the concentrations of fructosamine and glucose were measured at the time of admission to a coronary care unit. An OGTT was performed after 6-8 weeks. An abnormal fructosamine level yielded a positive predictive value of 58%, a sensitivity of 78% and a specificity of 95% (table 2.5). These values for random plasma glucose (discrimination value 7.8 mmol/l) were 17%, 100% and 52%, respectively. Thus, in a population with a high incidence of acute stress-related hyperglycaemia, the fructosamine measurement provides a better method to screen for DM than the randomly measured glucose concentration.

In summary, fructosamine has little value when used to screen for IGT. When used to screen for DM and IGT the test may be appropriate. For diagnosis of either DM or IGT the fructosamine measurement is inadequate. However, as mentioned for HbA1c, fructosamine measurement may be more sensitive than the OGTT for tracing patients at risk for long-term complications of diabetes mellitus. Finally, fructosamine measurement has an interesting potential for discriminating between stress-related hyperglycaemia and DM in a specific population such as that in a coronary care unit.
2.3.5.3 Glycated serum proteins and pregnancy

**Glycated serum proteins in normal pregnancy**

In normal pregnancy the GSP concentration has been reported to be the same or slightly lower than in the non-pregnant state (Lim and Staley, 1985; Roberts and Baker, 1986). Using affinity chromatography for GSP measurement, Nelson and co-workers (1985) found the concentration to be stable between the 18th and 34th week of gestation. In contrast, Roberts and Baker (1986) reported a gradual decrease of the fructosamine concentration in the course of pregnancy. In pregnant patients with a normal OGTT, we also reported a slight but significant decrease of the fructosamine concentration in the course of normal pregnancy (Van Dieijen-Visser and Salemans, 1986(a)). Our data will be reported in chapter 6. Since the decrease is very small, there is no need to correct the fructosamine concentration for gestational age.

**Glycated serum protein measurement for screening of gestational diabetes**

Gestational diabetes are, by definition, those women in whom impaired glucose tolerance or diabetes mellitus is first detected during pregnancy. Gestational diabetes has been associated with increased perinatal morbidity and mortality, and it is claimed that early diagnosis and treatment improves foetal outcome (O'Sullivan et al., 1973(a); Gabbe et al., 1977(a); Coustan and Imarah, 1984).

It is still common practice to subject pregnant women to an OGTT when there is 'clinical risk' of gestational diabetes. With this procedure, at best 50-60% of gestational diabetics will be detected (O'Sullivan et al., 1973(b)). Screening all pregnant women by blood glucose measurement 1 hour after a 50 g oral glucose load (cut-off value venous plasma glucose concentration 8.2 mmol/l) will identify 79% of gestational diabetics (O'Sullivan et al., 1973(b)). However, this 50 g screening test is associated with an appreciable false positive rate and is inconvenient, time-consuming and cumbersome in a busy antenatal clinic. It follows that there is a need for a simple and reliable screening method for gestational diabetes.

This led various investigators to study the value of GSP measurement as a screening method for gestational diabetes. Roberts and co-workers (1983) measured the fructosamine concentration in 20 women with gestational diabetes and in 79 non-diabetic pregnant women. The fructosamine test discriminated well between the two groups as 17 out of 20 gestational diabetics were detected, with only 4 false positive subjects out of 79 controls. However, a major shortcoming of this study was that the results were obtained in patients selected on the basis of an abnormal OGTT. This selection implies that no conclusions can be drawn about the screening value of fructosamine measurement in an unselected population.

In another study the screening value of fructosamine measurement was studied in 1200 women at the time of intake, 28 weeks and 36 weeks gestation (Roberts and Baker, 1986). In only 167 of these patients was an OGTT performed because of clinical risk factors. No information was obtained about the glucose tolerance in the
remaining 1033 patients. The authors' conclusion about the usefulness of fructosamine measurement as a screening test for gestational diabetes applies only to the selected OGTT population. Moreover, the degree of glucose intolerance in the gestational diabetics studied (n = 9) was much higher than in other studies [Al-Shawaf et al., 1988(a), 1988(b)], which may have improved the screening value of the fructosamine test in the former study.

Data on this subject from our clinic indicate that the fructosamine test is insensitive for use as a screen for gestational diabetes. Details of this study will be presented in chapter 5.

Glycated serum proteins and birth weight

The most important reason why gestational diabetics need to be detected, is to prevent the sequelae of maternal hyperglycaemia in their offspring. Gestational diabetes has been related to foetal macrosomia which is associated with an increased risk of traumatic delivery, shoulder dystocia, and/or Caesarean section (Gabbe et al., 1977(a)). Since poor glycaemic control in diabetic pregnancy often results in macrosomia and strict glucose control yields lower rates of foetal macrosomia, the level of glycaemic control during diabetic pregnancy seems to influence foetal growth and subsequent newborn weight. As the GSP concentration is an index of glucose control over the preceding 1-3 weeks, this variable could theoretically have a predictive value with respect to the risk of macrosomia in (gestational) diabetic women.

In 30 pregnant diabetics, the relationship was determined between the fructosamine concentrations at different stages of gestation and birth weight (Roberts and Baker, 1987). Diabetic mothers giving birth to macrosomic children had a higher first trimester fructosamine concentration than those producing an infant with a normal birth weight. The reports on the correlation between second and third trimester fructosamine values and birth weight are rather conflicting for both non-diabetic and diabetic pregnancy (Roberts and Baker, 1987; Fadel et al., 1986; Roberts et al., 1988). Therefore, more studies are needed to determine the relation between the fructosamine concentrations during pregnancy and the birth weight.

Glycated serum proteins in neonatal cord blood

In non-diabetics, John and co-workers (1985) reported higher concentrations of glycated albumin in mothers relative to their babies while the foetal and maternal values were found to be correlated. Reports on the GSP concentration in neonatal cord blood are conflicting, with no conclusive data that the GSP concentration in cord blood of infants of (gestational) diabetic mothers differs consistently from that of non-diabetic controls (John et al., 1985; Roberts et al., 1983; Fadel et al., 1986; Roberts and Baker, 1987; Roberts et al., 1988).

It follows that the clinical relevance of cord GSP measurement is yet to be ascertained.
2.4 Non-enzymatic glycation of other proteins

Retinopathy, neuropathy and proteinuria were already known to be associated with diabetes mellitus before the discovery of insulin. With the introduction of insulin therapy in diabetics the survival rate increased markedly. However, the increased life expectancy in diabetics allowed slow metabolic side effects of the disease to outgrow to health threatening complications such as nephropathy, microangiopathy and atherosclerosis. Since patients with prolonged poor glycaemic control experience more severe complications of diabetes mellitus more often, these complications are generally considered to be associated with hyperglycaemia. However, not all such patients develop complications. About 20-25% of IDDM patients do not develop any complications at all, despite long-term disease and only moderate glycaemic control. On the other hand, about 5% of IDDM patients develop severe complications in spite of adequate glycaemic control and short duration of the disease. The exact cause of this discrepancy is not known.

A number of hypotheses have been proposed to explain the pathogenesis of the complications. A plausible explanation has been given recently on the basis of a combined genetic and metabolic factor (Raskin and Rosenstock, 1986). A concerted action of hyperglycaemia and some genetic predisposition triggers the development of the typical complications.

One mechanism by which hyperglycaemia can lead to tissue damage is by an increasing influx rate of glucose into various metabolic pathways. Intracellular hyperglycaemia, which occurs preferentially in insulin-independent tissues such as eye lens and nerves, may interfere with normal cell metabolism, which eventually leads to secondary cell damage. These processes have been reviewed by Brownlee and Cerasi (1981).

Another mechanism by which hyperglycaemia leads to tissue damage is by non-enzymatic glycation. There is increasing evidence that non-enzymatic glycation of proteins, which is accelerated by hyperglycaemia, causes the central pathological features of diabetic complications (Brownlee et al., 1984(a), 1988).

Altered of physiological processes by non-enzymatic glycation

The discovery of increased non-enzymatic glycation of haemoglobin and serum proteins in hyperglycaemic diabetics has raised interest in glycation of other body proteins. An important reason is the supposition that this phenomenon could play a crucial role in the pathogenesis of long-term diabetic complications. Non-enzymatic glycation of proteins seems to occur in most body tissues where it may interfere with the biological function of proteins, giving rise to alterations in physiological processes. Several of these processes, affected by non-enzymatic glycation, have been reviewed by Brownlee and associates (1984(a)).
Alteration of enzyme activity

Although enzymes have relatively short half-lives, their catalytic properties may be altered by non-enzymatic glycation. Enzyme inactivation is often a result of glucose attachment to a functionally essential lysine ε-amino group. This form of inactivation has been illustrated in the enzyme ribonuclease A (Eble et al., 1983). In vitro, loss of enzyme activity associated with glycation has also been described for cathepsine B (Coradello et al., 1981), β-N-acetyl-D-glucosaminidase (Dolàofer et al., 1982) and alkaline phosphatase (Pollak et al., 1983).

Binding of regulatory molecules

Binding of regulatory molecules can alter the functional activity of some proteins. When binding of regulatory molecules requires unsubstituted amino groups, non-enzymatic glycation can interfere with effector-molecule binding. This may impair the molecule’s functional activity. The reversible binding of 2,3-diphosphoglycerate (2,3-DPG) to haemoglobin may serve as a model for regulatory molecule binding. As described in 2.2.3, binding of 2,3-DPG to the haemoglobin molecule reduces the affinity of haemoglobin for oxygen. Therefore, blockage of the binding site of 2,3-DPG by glycation increases oxygen affinity of the haemoglobin molecule (Bunn and Briehl, 1970).

The activity of the protein antithrombin III is also dependent on binding of regulatory molecules. After binding of heparin, antithrombin III becomes the major inhibitor of activated coagulation factors in plasma. In-vitro studies demonstrated that non-enzymatic glycation of antithrombin III diminishes this effect, which implies that the threshold of the coagulation cascade is reduced. This, in turn, may contribute to the accumulation of fibrin in various diabetic tissues (Brownlee et al., 1984(b)).

Cross-linking of proteins

Ketoamines on proteins with long half-lives may undergo a series of irreversible reactions, resulting in the formation of advanced glycation end products (Cerami et al., 1987). These products are involved in cross-linking of proteins. This process was first demonstrated in the lens protein α-crystallin (Stevens et al., 1978). In crystallin solutions containing 50 mM glucose, the development of opalescence was greatly accelerated. This opacification was found to be due to the formation of disulphide cross-links in glycated crystallins. The cross-linking resulted in the formation of high molecular weight, light-scattering protein aggregates. Besides non-enzymatic glycation, in vivo, also other processes associated with intracellular hyperglycaemia appear to be involved in the development of cataracts in diabetics (Cerami et al., 1979).

Studies of the dura mater of diabetics and non-diabetics has provided evidence that advanced glycation end products accumulate on collagen (Monnier et al., 1984). Some of the advanced glycated end products on collagen are capable of forming covalent bonds with amino groups on other proteins. In this way intercollagen
bonds are formed, resulting in enhanced stiffening and loss of elasticity of tissue. The accumulated end products may also form covalent cross-links with other proteins such as albumin, IgG and low-density lipoproteins (LDL). Trapping of albumin in collagen of basement membranes has been associated with the thickening of these membranes in diabetics (Sensi et al., 1986), while trapping of IgG may result in complement activation and immune-complex formation in diabetics (Brownlee et al., 1984(a)). Finally, LDL trapping in collagen could contribute to the accelerated development of atherosclerosis in diabetics (Brownlee et al., 1985).

Decreased susceptibility to proteolysis
Several in-vitro experiments have shown that some glycated proteins are more resistant to physiological degradation. In vivo, this has been demonstrated for glycated glomerular basement membranes (Lubec and Pollak, 1980) and glycated fibrin (Brownlee et al. (1983). This phenomenon could explain why glycated fibrin accumulates in diabetics in retinal capillaries, glomerular basement membranes and several other tissues. The accumulation of fibrin may also contribute to capillary and arteriolar occlusion, resulting in loss of functional glomerules and development of diabetic retinopathy and neuropathy (Timperly et al., 1976; Cutha-Vaz, 1978).

Function of nucleic acids
In spite of the low reactivity of nucleic acids with reducing sugars, these acids are also subject to non-enzymatic glycation. Since nucleic acids are long-lived molecules in the resting cells, the accumulation of glycation products in these cells could play a role in biological aging (Bucala et al., 1984). Acceleration of this process by hyperglycaemia may be the cause of the decreased capacity of the fibroblast to replicate in diabetics (Vranko and Beaditt, 1975). In an in-vitro study, Nanjou and co-workers (1986) provided evidence that oxygen radicals, generated during autooxidation of the ketosamines, induce site-specific damage in DNA. This observation supports the concept that the development of congenital anomalies in children of diabetic mothers may be caused by non-enzymatic glycation of DNA.

Macromolecular recognition and endocytosis
Most human cells have surface receptors. Each of these receptors recognizes a particular chemical structure. Binding of a chemical compound to its specific receptor on the cell membrane initiates a chain of events within the cell which culminate in a specific response. Fibroblasts have low-density lipoprotein (LDL) receptors; binding to the receptor results in endocytosis of the cholesterol-rich LDL. This process is important in order to keep plasma LDL at a low level. When the LDL-receptor function is impaired or the LDL structure is changed, endocytosis is reduced. The LDL concentration in plasma and, with it, the cholesterol deposition in tissue will rise. In-vitro studies with non-glycated and glycated LDL have shown that the endocytotic activity of cultured human fibroblasts towards glycated LDL was significantly reduced (Gonen et al., 1981). Accumulation of cholesterol is a typical feature
of atherosclerosis and known to be more prevalent in diabetic patients (Garcia et al., 1974). This accumulation may be the result of both cross-linking of glycated LDL to matrix components and decreased endocytosis of glycated LDL. In contrast to the impaired recognition of glycated LDL by fibroblasts, a macrophage receptor has been identified that specifically recognizes those proteins to which advanced glycation end products are bound. These receptors enable macrophages to remove these proteins (Radoff et al., 1987). When advanced glycation end products on myelin are recognized by macrophages, the complex will be taken up. This process may be involved in the segmental demyelination observed in diabetics as well as in normal aging.

Studies in both animals and humans have shown that non-enzymatic glycation of proteins, especially formation of advanced glycation end products, affects several physiological processes. Since many of these processes are impaired in diabetics and formation of advanced glycation end products is accelerated during hyperglycaemia, this strongly suggests that the central pathological features of various long-term diabetic complications are the result of non-enzymatic glycation. Support for this hypothesis comes from a recent study where the formation of advanced glycation end products was inhibited pharmacologically by aminoguanidine hydrochloride. In this study in diabetic rats, an increase in the thickness of the glomerular basement membrane was successfully prevented by aminoguanidine (Brownlee et al., 1988). With the discovery of a method for inhibiting the formation of advanced glycation end products, it has become possible to evaluate more accurately the role of this phenomenon in the development of chronic diabetic complications. In the future, pharmacological inhibition of the formation of advanced glycation end products may contribute to the prevention of structural lesions due to diabetes mellitus.

Chapter 3

The fructosamine assay

3.1 Principle of the fructosamine assay

In 1982 Johnson and co-workers introduced the fructosamine test, a new colorimetric method for the quantitation of GSPs (figure 2.1). The test is based on the ability of ketoamines (fructosamines) to reduce nitroblue tetrazolium (NBT) in an alkaline solution. In this medium, the reducing activity of ketoamines can be quantitated without significant interference from other reducing substances such as glucose and labile Schiff's bases (Gottschalk, 1952; Johnson et al., 1982). Fructosamine in alkaline medium is transformed to eneaminol which reduces NBT. This reduction is paralleled by the formation of formazan, a compound which can be measured spectrophotometrically (figure 3.1). The rate of formazan formation is directly proportional to the fructosamine concentration.

The exact mechanism of the reduction of NBT by fructosamine is not yet clear although, according to a recent report, a superoxide radical intermediate may be involved (Jones et al., 1987; figure 3.1).

3.2 Measurement of the serum fructosamine concentration

In the present study we used the fructosamine assay according to Johnson and co-workers (1982) with test kits from Roche Diagnostics, Basel, Switzerland (product no. 0711217). Serum samples were analysed on a Cobas® Bio centrifugal fast
analyser (Roche). 20 µl of serum and 50 µl of deionized water were mixed with 200 µl of reagent, containing 0.25 mmol/l NBT in 100 mmol/l sodium carbonate buffer at pH 10.35 (25°C). After incubation for 10 minutes at 37°C, the increase of absorbance at 530 nm was measured between 10 minutes and 15 minutes after the start of the reaction. The 10 minutes incubation time is necessary to allow fast reacting interfering substances such as ascorbate and glutathione to react (Johnson et al., 1982). Because glucose reduces NBT at a pH above 11 but does not react between pH 10 and 11, there is no need to remove endogenous glucose from the patients’ blood samples. The calibrator in the test kit contained a glycated protein standard, calibrated on 1-desoxy-1-morpholino-fructose (DMF), a synthetic Amadori rearrangement product. In each run two or three different control sera were included for additional assay control. The fructosamine concentrations were calculated according to the equation:

\[
\frac{(A_{t=15\text{min}} - A_{t=10\text{min}}) \text{ sample}}{(A_{t=15\text{min}} - A_{t=10\text{min}}) \text{ standard}} \times [C] \text{ standard}
\]

\(A_t\): absorbance at 530 nm at time \(t\)

\(C\): fructosamine concentration in mmol/l

3.3 Evaluation of the assay

3.3.1 Linearity of the assay; effect of dilution of the sample

The relation between the absorbance at 530 nm and the fructosamine concentration is linear up to 8 mmol/l DMF equivalents (Johnson et al., 1982), as has been confirmed by own (unpublished) results. Samples with fructosamine concentrations exceeding 8 mmol/l should be diluted.

The effect of serum sample dilution on the fructosamine concentration was studied as follows. A 1:1 dilution of 15 serum samples in distilled water or saline gave rise to an overestimation of the fructosamine concentration by about 20% (table 3.1). Dilution with various albumin-containing solutions led also to an overestimation. Overestimation could only be prevented by diluting the serum under investigation in pooled serum (table 3.1). The skewing caused by dilution in protein-free fluids is probably a result of the matrix-dependent optical absorbance characteristics of formazan (Johnson et al., 1982). The optical density of a given formazan solution varies depending on the composition and concentration of proteins in the diluent solution.

3.3.2 Assay precision

To evaluate the assay precision, intra-run and inter-run variations were determined. The intra-run precision was estimated by analysing, in 20-fold, 5 control sera in one single run. The inter-run precision was obtained by repeating the analysis of these 5 control sera daily over a period of 10 days. The results are listed in table 3.2. The low intra-run as well as inter-run assay variation agree well with reports of other investigators (Zeyen et al., 1986; Koskinen et al., 1987; Kverneland et al., 1987), and emphasize the high precision of the method.

3.3.3 Effect of freezing, thawing, and long-term storage on the fructosamine concentration

In the laboratory, serum is often stored in a freezer before analysis. To study the effect of freezing and thawing on the fructosamine concentration, two different batches of pooled sera were divided into aliquots and stored in a freezer at -20°C. Every time fructosamine measurements were performed, aliquots of the two pooled sera were also thawed and analysed. During a one year period, the fructosamine concentrations of the two frozen pooled sera remained virtually unchanged with coefficients of variation not exceeding the one determined for the inter-run assay (table 3.3). We therefore conclude that the fructosamine concentration is not affected by the long-term storage of serum at -20°C.

Furthermore, the fructosamine concentrations of lyophilized control samples (AutoNorm) were measured in every series of fructosamine measurements to serve as an extra control of the assay. These samples showed a slightly higher variation than did the pooled sera (table 3.3).

From the above, it follows that frozen pooled serum may be used as an (secondary) standard with confirmed stability for more than one year. The use of such a standard neatly overcomes matrix problems in the analysis.

CV: Coefficient of variation

3.4 Sensitivity to rapid glycaemic change

Non-enzymatic glycation of proteins is initiated by the formation of Schiff's base. This reaction between glucose and protein is reversible and the aldimine formed, if not eliminated during the assay, might cause rapid changes in the glycated protein concentration, as has been observed for glycated haemoglobin (Svendsen et al.,
1980). However, we confirmed the previously suggested (Lemon and Forrest, 1986; Mosca et al., 1987) negligible effect of rapid glycaemic changes on the fructosamine test in five randomly selected patients in whom an OGTT was performed. In the three hour period after the 75 g glucose load, a brief elevation in blood glucose concentration had no appreciable effect on the fructosamine concentration. The intra-individual (intra-run) variation within this period was less than 3% (table 3.4). Therefore, blood for fructosamine measurement can be sampled at any time during the day; analysis results are independent of the time since the last meal.

3.5 The influence of variations in the albumin or total protein concentration on the serum fructosamine concentration

It has been suggested that the serum fructosamine concentration is independent of the albumin or total protein concentration if the serum albumin concentration is higher than 30 g/l (Baker et al., 1983) or 35 g/l (Lloyd and Marples, 1984). In hospitalised subjects who are usually immobilised and in a supine position, the serum protein concentration is often reduced to a level below 30 g/l due to increased catabolism and redistribution of body water and albumin. Nevertheless, serum fructosamine concentrations in hospitalised non-diabetic patients were found to be comparable with those in ambulatory non-diabetic subjects (Lim and Staley, 1985). In order to define more precisely the role of serum proteins on the concentration of fructosamine, we studied the relation between these two variables. The serum concentrations of fructosamine, albumin and total protein were measured in 103 patients who had no obvious signs of diabetes mellitus and whose fasting glucose con-
centrations were below 5.5 mmol/l. The population sample studied included 84 patients with albumin concentrations above 30 g/l and 19 patients with albumin concentrations below 30 g/l. The serum fructosamine concentration was found to be correlated (p < 0.001) with both the serum albumin and total serum protein concentrations. The slope of the regression line calculated for the 84 patients with albumin concentrations above 30 g/l showed virtually no change when this group was supplemented with the 19 patients who had low albumin concentrations (table 3.5). This suggests that the mathematical relationship between fructosamine and serum protein is similar over the entire range of serum protein concentrations (21-46 g/l albumin) in this particular group of patients.

Table 3.5 Linear regression of serum fructosamine as the dependent variable (y) with serum albumin (g/l) and total serum protein (g/l) as the independent variables (x), respectively. The r represents the Pearson correlation coefficient.

<td>103</td>
<td>0.67</td>
<td>y = 0.023x + 0.44</td>
</tr>
</tbody>
</table>

All correlations are significant (p < 0.001)

From the regression equation in table 3.5 it can be deduced that a decrease in serum albumin of 1 g/l requires an increase of the fructosamine concentration actually measured with 0.026 mmol/l, or roughly 1% fructosamine correction per gram albumin change. For correction (standardisation) of the fructosamine concentration to 40 g albumin/l, the following equation can be used:

$$\text{Fr}_{\text{cor}} = \text{Fr} + 0.026 \times [40 - \text{Alb}]$$

where \(\text{Fr}_{\text{cor}}\) is the corrected fructosamine concentration (mmol/l), \(\text{Fr}\) represents the fructosamine concentration actually measured (mmol/l), and \(\text{Alb}\) the serum albumin concentration (g/l) measured concomitantly.

It goes without saying that correction for variations in the albumin concentration within the inter-run error of the albumin assay (CV = 5%) is trivial. Therefore, this correction is only recommended when the fructosamine concentration is measured intermittently in patients in whom the serum albumin concentration fluctuates over a wide range ( > 10 g/l). In general, correction of the fructosamine concentration for the albumin level is not necessary.

Chapter 4

Comparison of fructosamine, glycated haemoglobin and postprandial blood glucose concentrations as measures of glycaemic control in non-insulin dependent diabetics

(submitted for publication)

Summary

In this study we determined the value of fructosamine and HbA1 relative to that of postprandial glucose as measures of glycaemic control in patients with non-insulin dependent diabetes mellitus (NIDDM). To this end, the relation between venous plasma glucose two hours after breakfast, fructosamine and HbA1 was studied in 180 elderly NIDDM patients. The fructosamine and HbA1 concentrations were found to correlate with the glucose concentration two hours after breakfast \( r = 0.66, p < 0.0001 \) and \( r = 0.74, p < 0.0001 \), respectively. They were also related to each other \( r = 0.75, p < 0.0001 \). The strength of the correlation between fructosamine and the other two variables did not increase by correcting the fructosamine concentration for the albumin concentration.

A literature survey on the relation between glucose control, fructosamine and HbA1 is included for comparison with data published elsewhere. It is concluded that fructosamine may serve as an attractive alternative to HbA1 for control of the more recent glycaemic status in NIDDM patients.

67
Introduction

Effective management of diabetic patients requires a reliable method for the regular evaluation of the glycaemic status. Such a method should be accurate, easy to perform, and inexpensive. Moreover, the method should be independent of food intake and physical activity, in order to allow random measurement. Unfortunately, none of the methods currently employed measure up to all these criteria.

Nowadays, self-monitoring of blood glucose has gained widespread application in the clinical assessment of the glycaemic status. However, a drawback of self-monitoring is its dependence on patient compliance. Even in presumably well-motivated pregnant diabetics who were aware of the importance of normoglycaemia, it has been demonstrated that the self-reported glucose concentrations were significantly lower and less variable than the true glucose values simultaneously obtained with a memory-based reflectance meter (Langer and Mazze, 1986).

Fasting blood glucose measurement as an outpatient is inconvenient and it has been demonstrated that its value for evaluating the glycaemic status should be interpreted with caution, especially in insulin-dependent diabetics (Service et al., 1987).

In order to check the glycaemic status, the value of random blood glucose measurement is limited because the blood glucose concentration in diabetics depends on many factors and may fluctuate widely.

As food ingestion forms the most important challenge for endogenous blood glucose control, the postprandial blood glucose measurement provides useful information about the body’s capacity to prevent the blood glucose concentration increasing excessively. In the management of diabetics, the peak in venous plasma glucose concentrations 90 to 120 minutes after a meal should not exceed 11.1 mmol/l (WHO Report, 1985). However, the peak in postprandial blood glucose may be difficult to determine as it varies with intestinal absorption, carbohydrate composition and quantity in the meal, and physical exercise in the period between meal and blood sampling (Service et al., 1983; Bantle et al., 1983). Nevertheless, the method is commonly used in the management of diabetics.

In contrast to the glucose concentration, the concentration of non-enzymatically glycated proteins provides indirect information on glucose control over a prolonged period. The glycated haemoglobin (HbA1) concentration reflects the mean blood glucose concentration over the preceding 6–10 weeks (Koenig et al., 1976; Gonen et al., 1977; Cabbay et al., 1977; Bunn et al., 1978), whereas the glycated serum protein (GSP) concentration is an estimate of the average blood glucose concentration over the past 1–3 weeks (Mc Farland et al., 1979; Dolhofer and Wieland, 1979). These characteristics of the latter two variables imply that the information generated is complementary to glucose measurements. Since these tests are not influenced by short-term fluctuations in blood glucose level (chapter 3), they are independent of patient compliance and can be determined irrespective of the times of meals. Unfor-
tunately, the introduction of the HbA₁ and GSP measurements as routine clinical methods in the management of diabetics has often been hampered by the laborious and expensive measurement techniques required.

Johnson and co-workers (1982) described a simple, cheap, rapid, automated and precise method for measurement of the GSP concentration, the so-called fructosamine assay. To determine whether the measurement of the fructosamine concentration may be an alternative to the currently used parameters of glucose control in NIDDM patients, we compared the fructosamine concentrations with simultaneously measured plasma glucose concentrations two hours after breakfast and with HbA₁ concentrations.

Patients

During a period of sixteen months ending January 1989, 180 elderly NIDDM patients at the diabetic clinic of the De Wever Hospital in Heerlen agreed to participate in this study. The group comprised 64 males and 116 females. Their ages ranged from 34 to 88 years with a mean of 67 years. Diabetic control was accomplished by diet, occasionally supplemented with oral hypoglycaemic drugs. In many elderly patients glycaemic control was poor, often due to low motivation to comply with the treatment regimen advised. The patients were instructed to have their blood sampled at the time of their subsequent visit at 2 hours after breakfast. The concentrations of plasma glucose, fructosamine, HbA₁, and albumin were determined in this sample.

Analytical techniques

Glucose

Blood for venous plasma glucose measurement was collected into tubes containing fluoride (Sarstedt). Immediately after centrifugation at 3000 rpm for 5 minutes, the plasma sample was analysed on a Cobas® Bio centrifugal fast analyser using the Gluco-quant glucose test combination (Boehringer, Mannheim, Germany; product no. 245178). This test is based on the hexokinase/glucose-6-phosphate dehydrogenase reaction.
Glycated haemoglobin

For the measurement of glycated haemoglobin, 5 ml blood was collected into tubes containing K2H2EDTA. The analysis was performed with the haemoglobin A1 column-exchange column test (Biorad, Richmond, USA; product no. 1917001).

Fructosamine

The fructosamine assay was performed according to Johnson et al. (1982). The test is based on the non-enzymatic formation of fructosamine from glucose and proteins, which can be quantitated by nitroblue tetrazolium reduction in an alkaline medium. Serum samples were analysed on a Cobas® Bio centrifugal fast analyser with instrument setting as described by Roche (Roche Diagnostics, Basel, Switzerland; product no. 0711217) (see chapter 3). In table 4.1 the assay precision, time of analysis and costs of the HbA1c determination are compared with those of the fructosamine determination. The fructosamine measurement has a better intra-run and inter-run precision, and is less time-consuming and expensive than the micro-column HbA1c measurement.

Albumin

Serum albumin was measured on a Cobas® Bio centrifugal fast analyser using Bromocresol green as a reagent (Electro-Nucleonics, Breda, Netherlands; product no. R5-1). Albumin concentrations were measured to allow correction of fructosamine concentrations by using the following equation:

\[ Fr_{corr} = Fr + 0.026 \times [40 - Alb], \]

where \( Fr_{corr} \) is the corrected fructosamine concentration (mmol/l), \( Fr \) represents the measured serum fructosamine concentration (mmol/l) and \( Alb \) the measured serum albumin concentration (g/l) (chapter 3).
Statistical analysis

Correlations were determined by linear regression analysis with the least squares method. A probability of less than 5% (p<0.05) was considered significant.

Results

The relations between the various parameters are presented as scattergrams in figure 4.1 (A, B, C). Both the fructosamine and the HbA\textsubscript{1c} concentrations correlated with the postprandial glucose level. A correlation was also found between the fructosamine and HbA\textsubscript{1c} concentrations. Correction of the fructosamine concentration for the albumin concentration did not improve the correlations. The mean values, standard deviations and ranges of the measurements are listed in table table 4.2, whereas the correlation coefficients for each of the relationships tested are presented in table 4.3. All correlations are highly significant (p<0.0001).

Discussion

In diabetics, maintenance of normoglycaemia either by diet, oral hypoglycaemic drugs or insulin is important to reduce diabetic symptoms and to prevent or delay specific complications commonly associated with the disease. Various prospective trials have provided evidence that long-term near normoglycaemia may postpone the development and/or diminish the severity of late diabetic complications (Deckert et al., 1983; Holman et al., 1983; Raskin et al., 1983; Dahl-Jorgensen et al., 1986).

In clinical practice, routine diabetic control is often performed by measuring the glucose concentration 90 to 120 minutes after a meal. In NIDDM patients we have shown that both the fructosamine and the HbA1 concentrations correlate well with the glucose level 2 hours after breakfast, an observation in agreement with the results from a recent study in 104 NIDDM patients (Smart et al., 1988). Although the fructosamine concentration does co-vary with the serum albumin concentration (chapter 3), this relationship has little practical consequence for ambulatory patients. This is suggested by the lack of improvement in the correlation between fructosamine and postprandial glucose levels when the fructosamine concentrations were 'standardised' at 40 g/l albumin, in spite of a wide variation in albumin concentrations (28-47 g/l).

Table 4.4 presents a review of the literature on relations between glucose control, fructosamine and HbA1c. This table illustrates that most studies in diabetics report a good correlation between the fructosamine and HbA1c concentrations on the one hand and the quality of glucose control on the other. The correlations are not influenced by the method of HbA1c measurement. From table 4.4 it can also be deduced that in NIDDM patients both the fructosamine and HbA1c measurements provide a better estimate of glycaemic control than in IDDM patients (Mosca et al., 1987; Smart et al., 1988). This may be related to the narrower range between which glucose fluctuates in NIDDM than in IDDM patients. Although most authors report good correlations between glucose control, fructosamine and HbA1c, it should be emphasized that the wide variations of glucose concentrations in the patients studied have some positive effect on the correlations. For clinical practice one should realize that small short-term oscillations in glucose level around the mean have virtually no influence on the fructosamine and HbA1c concentrations. It is likely that the low screening value of the fructosamine and HbA1c measurements for identifying patients with impaired glucose tolerance is a consequence of this characteristic (Salemans et al., 1987).

* As concluded from published figures
- No data

Method of HbA<sub>1</sub> measurement:
- a High performance liquid chromatography
- b Microcolumn, affinity chromatography
- c Electrophoresis, cellulose acetate
- d Microcolumn, ion-exchange
- e Colorimetric thiobarbituric acid method (Flückiger)
- f Isoelectric focusing
Fructosamine measurement has been found by many investigators to be as valuable as HbA1 measurement for use in the evaluation of the glucose control over a period up to 4 weeks, especially in NIDDM (table 4.4). Because fructosamine measurement is less expensive and easier to perform than most HbA1 measurement techniques, the former should be preferred for this purpose. Moreover, the fructosamine measurement is theoretically preferable to the HbA1 measurement for the estimation of glucose control over the preceding 4 weeks; fructosamine, with a half-life of 2-3 weeks, provides a better representation of the glycaemic status over this period than HbA1, which has a half-life of 10 weeks. This presumption also implies that the HbA1 determination should be held as the method of choice for the assessment of long-term glycaemic control (table 4.4, Daubresse et al., 1987), especially in patients with IDDM.

In short, both fructosamine and HbA1 seem to deserve a place in the evaluation of the glycaemic control in diabetics and may be regarded complementary rather than competitive tests.

Chapter 5

The value of fructosamine and haemoglobin A₁ measurements for screening and diagnosis of impaired glucose tolerance, diabetes mellitus and gestational diabetes

T.H.B. Salemans, M.P. Van Dieijen-Visser, P.J. Brombacher.

Part of this study has been published in Annals of Clinical Biochemistry 24: 447-452, 1987.
(with permission)

Summary

In this study the value of fructosamine and HbA₁ measurements as screening and diagnostic tests for impaired glucose tolerance (IGT), diabetes mellitus (DM), and gestational diabetes was assessed in a selected population. Patients were classified on the basis of standard 75 g oral glucose tolerance tests (OGTT).

In non-pregnant patients with IGT (n = 41) or DM (n = 56) both fructosamine and HbA₁ concentrations were elevated relative to control patients (n = 96) and to patients with a normal OGTT (n = 215). The value of fructosamine and HbA₁ measurements as screening tests for IGT and DM could be demonstrated by a simple yet sophisticated analytical technique, the receiver operating characteristic curve. On the other hand, the diagnostic value of these tests for IGT and DM was disappointing.

In patients with gestational diabetes (n = 14), the fructosamine and HbA₁ concentrations were similar to those in control patients (n = 88) and in pregnant patients with a normal OGTT (n = 236). It was demonstrated that in the pregnant population studied, fructosamine and HbA₁ measurements both lacked screening as well as diagnostic power with respect to gestational diabetes.
Introduction

The HbA₁ concentration is nowadays generally considered to provide valuable retrospective information about the quality of glycaemic control in patients with diabetes mellitus; the HbA₁ concentration correlates well with the mean blood glucose concentration over the preceding 6-10 weeks (Koenig et al., 1976; Bunn et al., 1978). Since the first reports on HbA₁, this phenomenon has led several investigators to study the value of this variable for identifying patients with impaired glucose tolerance (IGT) or diabetes mellitus (DM). However, interpretation and comparison of the reported values is difficult due to the lack of uniformity in selecting the upper limit for a normal HbA₁ concentration and differences in conducting and interpreting the OGTT (Dods and Boinney, 1979; Dix et al., 1979; Miedema and Casparie, 1984; Albett et al., 1985).

Because the fructosamine concentration provides information about the glycaemic status over the previous 1-3 weeks, its measurement has (in comparison to HbA₁) promising potential as a screening and/or diagnostic test for IGT, DM and gestational diabetes (Baker et al., 1983; Roberts and Baker, 1986). However, the tests have not yet been thoroughly evaluated for this purpose.

The present study was designed to evaluate the use of fructosamine and HbA₁ measurements as screening and diagnostic tests for IGT, DM and gestational diabetes.

Patients

Non-pregnant patients suspected of diabetes mellitus

During a two-year period ending in July 1987, 312 consecutive patients (163 women, 149 men) suspected of having diabetes mellitus were studied. All were referred for an OGTT. Their ages ranged from 13 to 82 years. Reference values of HbA₁ and fructosamine concentrations were obtained from a group of 96 healthy subjects of comparable age without signs of diabetes mellitus and with fasting venous plasma glucose concentrations below 5.5 mmol/l.

Pregnant women suspected of gestational diabetes

A total of 250 pregnant women between 17 and 43 years of age were screened for gestational diabetes by an OGTT during an eighteen-month period ending in Janu-
ary 1987. These patients were selected on the basis of classical risk factors, such as age over 30 years, obesity, family history of DM and excessive growth of the uterus. The reference group for these 250 patients consisted of 88 randomly selected healthy pregnant women of comparable age attending the antenatal clinic, but without suspicion of gestational diabetes and having fasting glucose concentrations below 5.5 mmol/l. Their ages ranged from 19 to 40 years.

Methods

Oral glucose tolerance test (OGTT)

Patients were instructed to take an unrestricted diet with more than 150 g of carbohydrate daily for at least three days prior to testing. The OGTT was performed after an overnight fast of 10-16 hours. Smoking was not permitted during the test. Each patient was given an oral dose of 75 g of glucose in 250-300 ml of water. Venous plasma glucose concentrations were measured in a fasting blood sample and in five samples obtained 30, 60, 90, 120 and 180 minutes after the glucose intake. In accord with the WHO criteria (1985), only the fasting glucose concentration and that 2 hours after a 75 g oral glucose load were used for classifying the result of the OGTT. The same cut-off values were used in pregnant and non-pregnant patients. Diagnostic interpretation of the OGTT is summarized in table 1.1. According to the WHO criteria, three groups of non-pregnant patients were formed: normal glucose tolerance, impaired glucose tolerance (IGT) and diabetes mellitus (DM). In the pregnant patients the following groups were formed: normal glucose tolerance, gestational impaired glucose tolerance (GIGT) and gestational diabetes mellitus (GDM). The term gestational diabetes was applied to patients with either GIGT or GDM.

Laboratory measurements

The techniques by which glucose, fructosamine, HbA1, and albumin were measured, have been described in chapter 4. Fructosamine, HbA1, and albumin concentrations were measured in a blood sample withdrawn together with that for the fasting blood glucose sample during the OGTT. Serum for later measurement of fructosamine and albumin was stored at −20°C before analysis. Because the fructosamine concentration may be influenced by the albumin concentration, the latter was measured to allow correction of the fructosamine concentration to a standard albumin concentration (for correction method see chapter 3).
Statistical analysis

Correlations were determined by linear regression analysis with the least squares method. Differences between means were evaluated by Student's unpaired t-test. A probability of less than 5% (p < 0.05) was considered significant. The value of fructosamine and HbA1 levels as screening and diagnostic tests was determined by constructing receiver operating characteristic (ROC) curves (Sackett et al., 1985; Richardson et al., 1985). The value of this method lies in providing a clear graphic analysis of the screening and diagnostic possibilities of a test over its entire range of values.

Results

Non-pregnant subjects

The results obtained in the non-pregnant subjects are listed in table 5.1. Both the fructosamine and the HbA1 concentrations were higher in the IGT patients than in controls and patients with a normal OGTT (p < 0.05). In patients with DM, the fructosamine and HbA1 levels were higher still than those in the IGT group (p < 0.01). Correction of fructosamine to a standard albumin concentration had no appreciable effect on the differences between the various patients groups.

The sensitivity, specificity and predictive values (table 2.2) of fructosamine and HbA1 measurements for the combined DM/IGT group and for the DM group alone are listed in table 5.2. The upper limits for normal fructosamine and HbA1 concentrations (cut-off values) were defined as the value which was 2 SD
above the mean for the control group (2.55 mmol/l and 8.6%, respectively). The sensitivity of fructosamine for identifying patients in the combined IGT/DM group and in the DM group alone was slightly higher (43% and 63%, respectively) than that of HbA₁ (34% and 55%, respectively). In contrast, the positive predictive value of HbA₁ in the two groups (79% and 74%, respectively) was higher than that of fructosamine (71% and 59%, respectively).

To evaluate the sensitivity and specificity of fructosamine and HbA₁ measurements over their entire range of (cut-off) values, ROC curves were constructed (figure 5.1). The pattern of the ROC curves indicate that both tests do have screening potential. Figure 5.1 also illustrates that the sensitivity of fructosamine and HbA₁ measurement is similar at any given value for specificity, both for detecting patients with either IGT or DM (figure 5.1 (A)), and for detecting patients with DM (figure 5.1 (B)).

Pregnant subjects

The results of the fructosamine and HbA₁ measurements obtained in the pregnant subjects are listed in table 5.3. The fructosamine and HbA₁ concentrations in the gestational diabetics (GIGT) were comparable with those in control patients and patients with a normal OGGT (p>0.05).

Table 5.4 lists the sensitivity, specificity, and predictive values of HbA₁ and fructosamine measurements for gestational diabetes. The upper limits of normal for HbA₁ and fructosamine concentrations were defined as the values which were 2 SD above the means for the pregnant control group (7.8% and 2.30 mmol/l, respectively). Both fructosamine and HbA₁ measurements performed poorly in the detection of gestational diabetes. Only 3 of 14 (21%) gestational diabetics were the fructosamine concentration abnormal, whereas in only 1 of 14 (7%) of these patients was the HbA₁ percentage abnormal. Moreover, the positive predictive values of fructosamine and HbA₁ measurements were very low. In only 1 of 3 (33%) and 1 of 6 (17%) patients with abnormal fructosamine or HbA₁ values, respectively, was gestational diabetes diagnosed.
Furthermore, the ROC curves as shown in figure 5.2 indicate that neither fructosamine nor HbA₁ had any value as screening or diagnostic tests for gestational diabetes.

Discussion

Impaired glucose tolerance and diabetes mellitus

The OGTT has been used for decades as a reference method for defining patients with abnormal glucose tolerance. The OGTT is not a prerequisite for identifying patients with DM which can also be diagnosed on the basis of a fasting venous plasma glucose concentration of 7.8 mmol/l or higher. In the asymptomatic patient an additional test with a value in the diabetic range is desirable (WHO Report, 1985). On the other hand, IGT can only be diagnosed by means of an OGTT. One should however realize that the 'golden standard' (OGTT) has been associated with a certain false positive rate (O'Sullivan and Mahan, 1966; Siperstein, 1975). The response to an oral glucose load may be influenced by several factors such as drugs, physical activity, infection, and food intake (Siperstein, 1975). All these factors are known to reduce the reproducibility of the OGTT (Coelinho Bennink, 1980; O'Sullivan and Mahan, 1966; Kobberling et al., 1980).

HbA1 (Dods and Bolney, 1979) and fructosamine measurements (Baker et al., 1983) have both been suggested as alternative tests for detecting individuals with
IGT or DM. These tests are not influenced by the factors mentioned above and therefore offer practical advantages over (OGTT) glucose measurements. In the present study, the fructosamine and HbA₁ concentrations differed significantly between the patients with normal glucose tolerance on the one hand, and those with IGT or DM on the other (table 5.1). It was demonstrated that with respect to IGT and DM both fructosamine and HbA₁ measurements did have (similar) screening value; for each cut-off point selected, the true positive rate was clearly higher than the false positive rate. Whereas for screening purposes a distinct percentage of false negative results of a test is usually acceptable, for diagnostic purposes this is not. Moreover, a diagnostic test should incur few false positive results. Because the true positive rates of fructosamine and HbA₁ measurements with respect to IGT and DM only approximate to 100% for (low) cut-off values with concomitantly high false positive rates, the tests fail diagnostic power (figure 5.1).

The patterns of the ROC curves confirm that the average glucose concentration over a certain period as judged by fructosamine and HbA₁ levels provides information about a different aspect of glucose metabolism than the response to a non-physiological glucose load as measured by an OGTT. On the other hand, the correlations between the area under the OGTT-curve on the one hand and HbA₁ (r=0.67, p<0.001) or fructosamine concentration (r=0.53, p<0.001) on the other, indicate that these two aspects of glucose metabolism are interrelated.

The main advantage of early detection of subjects with impaired glucose handling is the prevention of long-term complications of the disease by early treatment. Diabetic complications develop as a direct consequence of chronic hyperglycaemia (Brownlee et al., 1984 and 1988) whereas normoglycaemia in these patients generally reduces the progression and severity of such complications (Raskin and Rosenstock, 1986). Since the fructosamine and HbA₁ concentrations reflect average glucose levels over a certain time interval, the information provided by these two variables may be more valuable than that given by the OGTT in the selection of patients who may benefit from treatment. Long-term studies are needed to determine the risk of diabetic complications in individuals in whom an abnormal OGTT is paralleled by a repeatedly normal fructosamine and/or HbA₁ concentration.

Gestational diabetes

Gestational diabetes is defined as glucose intolerance with onset or first recognition during pregnancy. The criteria for diagnosis are arbitrary and differ in various studies (National Diabetes Data Group, 1979; O'Sullivan et al., 1964; Abell, 1979; Coelingh Bennink, 1980; WHO Report, 1985). At any rate, many studies do report a higher perinatal morbidity in the offspring of gestational diabetics (Gabbe et al., 1977; Coustan and Imarah, 1984; Widness et al., 1985). Thus, screening for gesta-
Gestational diabetics appears to be important in terms of identifying patients with increased risk for developing these complications. To subject each patient to an OGGT is unfriendly to patients, cumbersome, time-consuming and expensive. Screening for gestational diabetes on the basis of clinical risk factors may result in 37% of the population requiring OGGTs with a false negative rate of about 33% (O'Sullivan et al., 1973; Gillmer et al., 1980). To our knowledge, the best documented screening test is measurement of the blood glucose concentration 1 h after a 50 g glucose load, regardless of the time since the last meal. By using a venous plasma glucose concentration of 7.7 mmol/l as cut-off value, approximately 8% of the population was selected for an OGGT (Gillmer et al., 1980). This approach appears to have reduced the false-negative rate to 21% instead of 33% (O'Sullivan et al., 1973). Screening by random blood glucose sampling has also been advocated (Lind and Anderson, 1984), but in a population with a high prevalence of IGT, the predictive value of this method was disappointing (Nasrat et al., 1986).

HbA₁c and fructosamine measurements have been claimed to represent elegant alternative screening methods for gestational diabetes when compared to the glucose challenge tests (Morris et al., 1986; Roberts and Baker, 1986). However, the low sensitivity of these tests as recently suggested by Contois and co-workers (1989) and confirmed by our own results, raises doubt about their value as screening tests. In this context it is important to stress the fact that the goal of screening for gestational diabetes should not be merely detection of an abnormal OGGT. The ultimate goal should be early detection of pregnant patients with elevated blood glucose levels in conditions of unrestricted food intake; only these patients require specific treatment in order to reduce the risk of the typical foetal and neonatal morbidity. It follows that fructosamine and HbA₁c may prove to be better tests than the OGGT for screening of pregnant patients at risk for hyperglycaemia-related foetal and neonatal complications.

Chapter 6

Fructosamine and glycated haemoglobin in normal pregnancy

Part of this study has been published in Annals of Clinical Biochemistry 23: 661-666, 1986.
(with permission)

Summary

Glycated haemoglobin (HbA1) and fructosamine concentrations were measured in 276 pregnant patients with a normal oral glucose tolerance test (OGTT). In the course of pregnancy the HbA1 concentration remained unchanged. The results were similar for a chromatographic (Biorad) and an electrophoretic (Corning) technique for HbA1 measurement.

In contrast, in the course of pregnancy a small but significant decrease in the fructosamine concentration was observed (r = -0.17, p < 0.01). This change appeared to be attributable to a concomitant decrease in the albumin concentration (r = -0.69, p < 0.0001). When the fructosamine concentration was corrected for the albumin concentration, the (corrected) fructosamine concentration remained unchanged throughout pregnancy. The decrease of the fructosamine concentration during pregnancy was so small that correction for albumin and/or gestational age in a clinical setting appears to unnecessary.

During normal pregnancy glucose tolerance decreased, as indicated by an increase of the area under the OGTT-curve (+ 17%) and a rise of the 2-hours OGTT glucose value (+ 24%). On the other hand, the fasting glucose concentration decreased by 10%. Balance between these opposite effects may explain why fructosamine and HbA1 concentrations in normal pregnancy change little.
Introduction

Measurement of the glycated haemoglobin (HbA\textsubscript{1c}) concentration is nowadays considered a useful parameter in the quality control of the glycaemic status over a prolonged period. The HbA\textsubscript{1c} concentration represents an indirect estimate of the mean blood glucose concentration over the preceding 6-10 weeks (Koenig et al., 1976; Gonen et al., 1977; Bunn et al., 1978). Recently, a highly practicable method, the fructosamine test, has been developed to measure the concentration of glycated serum proteins (GSPs) (Johnson et al., 1982; Baker et al., 1983; see also chapter 3). The much shorter half-life of GSPs than that of HbA\textsubscript{1c} not only offers interesting possibilities of obtaining indirect information about the mean glucose concentration during the preceding 1-3 weeks (Daubresse et al., 1987; Koskinen et al., 1987), but is also likely to respond faster to a change in the mean blood glucose concentration. In addition the GSP concentration may follow more closely changes in the mean blood glucose concentration than does the HbA\textsubscript{1c} concentration since the latter varies with the glucose concentration within the red cells rather than with that in serum.

Inasmuch as early recognition and subsequent treatment of maternal hyperglycaemia during pregnancy is important in reducing neonatal morbidity (Landon et al., 1987), both fructosamine and HbA\textsubscript{1c} measurements may be of help for identifying pregnant patients at risk of the sequelae of hyperglycaemia. As pregnancy is a dynamic state, the balance of many physiological processes changes continuously. Therefore, it is important that the study of the clinical applicability of fructosamine and HbA\textsubscript{1c} measurements during pregnancy should be preceded by a reference study which describes the changes in these two variables in the course of normal pregnancy. Reports on both the trend in fructosamine (Nelson et al., 1985; Roberts and Baker, 1986) and HbA\textsubscript{1c} concentrations (Schwartz et al., 1976; Lind and Cheyne, 1979; Leslie et al., 1978; Fadel et al., 1979) during pregnancy are conflicting. Part of the reported discrepancies appear to be due to the limited amount of data in these studies, whereas also the lack of consistency in the definition of 'normality' has contributed to the confusion.

The present study was designed to evaluate the relationship of fructosamine and HbA\textsubscript{1c} levels with gestational age. Pregnancy in this context was considered 'normal' when the 75 g OGTT had a normal outcome. The HbA\textsubscript{1c} concentration was measured by two different techniques. Because fructosamine predominantly consists of glycated albumin and the albumin concentration decreases in the course of pregnancy, we also studied the possible contribution of changes in this variable to the relation between fructosamine concentration and gestational age. Finally, the evolution of glucose tolerance in the course of normal pregnancy was described.
Patients

During a period of 20 months all pregnant women registered at the antenatal clinic and referred for an OGTT were informed about the study and invited to participate. These patients constituted approximately 20% of the total intake of pregnant patients in our clinic. They were selected on the basis of clinical risk factors for gestational diabetes. These factors included obesity, age over 30 years, clinical suspicion of a large foetus, family history of diabetes mellitus, polyhydramnios, glycosuria, and an obstetrical history suspected for gestational diabetes. The latter referred to a previous birth of a large infant, unexplained stillbirth and recurrent miscarriage. Patients in whom the OGTT was abnormal (n = 37) or in whom the expected date of confinement was not confirmed by first trimester ultrasound (n = 18), were excluded from the study. The remaining 276 patients with normal glucose tolerance and reliable expected dates of confinement were studied.

Methods

Oral glucose tolerance test

Standard 75 g OGTTs were performed according to WHO recommendations (1985) (see chapter 5). Diagnostic interpretation of the OGTT is summarized in table 1.1.

Laboratory measurements

The techniques by which glucose, fructosamine and albumin levels were measured, have been described in chapter 4. Both an ion-exchange chromatographic HbA1 microcolumn test (Biorad, product no. 1917001; intra-run precision 2-4%, inter-run precision 4-7%), and an electrophoretic HbA1 test (Corning, product no. 470055; intra-run precision 4-7%, inter-run precision 6-8%), were used for HbA1 measurement. Fructosamine, HbA1, and albumin concentrations were measured in a blood sample withdrawn together with that for the fasting blood glucose sample during the OGTT. Serum for later measurement of fructosamine and albumin was stored at -20°C.
Figure 6.1 Relation between serum fructosamine (A), HbA1c (B), serum albumin (C) concentrations, respectively, and gestational age. Also the relation between serum fructosamine and serum albumin concentrations (D) is shown. The linear regression lines (-----) including 95% confidence limits of regression lines (----------) and 95% prediction limits of sample points (------) are shown. The regression equations with their correlation coefficients are listed in Table 6.1.
Statistical analysis

Correlations were determined by linear regression analysis with the least squares method. A probability of less than 5% (p<0.05) was considered significant.

Results

The following parameters were correlated with gestational age: fructosamine, HbA1, albumin, fasting blood glucose, glucose 2 hours after glucose load and the area under the OGTT curve. The results are summarized in table 6.1.

* n = 162

Figure 6.1 (A, B, and C) illustrates the relationships between the fructosamine, HbA1, and albumin concentrations, respectively, on the one hand, and gestational age on the other. The relationship between fructosamine and albumin levels is illustrated in figure 6.1 (D).

It was demonstrated that the HbA1 concentrations as measured by two different techniques varied independently of the gestational age. Apart from that, the HbA1 concentrations measured by the chromatographic column method were systematically higher than those measured by the electrophoretic method (table 6.1).

Whereas the HbA1 concentrations varied independently of gestational age, the fructosamine concentrations decreased (p<0.01) with advancing pregnancy (figure 6.1 (A)). Although the slope of the regression equation for the relationship between the fructosamine (y; mmol/l) and the albumin concentration (x; g/l) was small (y = 0.01x + 1.69, r = 0.18, p<0.003; figure 6.1 (D)), it did have relevance: the con-
comitant decline in albumin and fructosamine concentrations in pregnancy suggests that the changes in fructosamine concentrations merely reflect those in albumin concentrations. This apparent covariance was confirmed by correction of the fructosamine concentrations for this albumin effect: the relationship between fructosamine concentration and gestational age disappeared.

The mean fasting blood glucose concentration decreased gradually in the course of pregnancy by a total of 0.52 mmol/l (-10%). In contrast, the near-term glucose concentration 2 hours after glucose load (+24%) and the area under the OGTT curve (+17%) had gradually increased in the course of pregnancy (table 6.1) indicating a fall in glucose tolerance with pregnancy.

Discussion

Glycated haemoglobin

In the present study HbA₁ varied independently of gestational age, an observation at variance with the results of most other studies in which HbA₁ was found to decrease in the first half of pregnancy (Lind and Cheyne, 1979; Hanson et al., 1983; Worth et al., 1985). It is possible that the lack of correlation between HbA₁ concentrations and gestational age in our study was caused by the cross-sectional set-up of the present study. The increased scatter associated with such a set-up may have masked a possible small decline in the HbA₁ concentrations in early pregnancy as reported by others. A decline in HbA₁ concentration in early pregnancy may be the result of a fractional rise in young erythrocytes in early pregnancy. These young cells with shorter exposure to the glycaemic environment are likely to have a lower HbA₁ fraction than mature erythrocytes (Hyttten and Lind, 1973). Data reported about the trend in HbA₁ concentration in the second half of pregnancy are also conflicting, with studies reporting either a rise (Phelps et al., 1983; Griffiths et al., 1987) or a fall (Hanson et al., 1983). These conflicting results appear to be related to differences in population samples as suggested by differences in fasting glucose concentrations; moreover, in these studies the glucose tolerance was not determined. Inasmuch as in the present study only those pregnant subjects were included who had a normal OGTT, our results provide information on the trend of the HbA₁ concentration in the course of pregnancies with confirmed normal glucose tolerance. In these patients HbA₁ concentrations were found to vary independently of gestational age.
Fructosamine

In the present study a small but consistent decrease in the fructosamine concentration in the course of pregnancy was found. Several authors also investigated the relationship between fructosamine and gestational age. Their results indicate either no change (Nelson et al., 1985) or a slight gradual decrease throughout pregnancy (Roberts and Baker, 1986). The latter study agrees with our data as we also found a weak negative correlation between fructosamine concentration and gestational age. However, the latter correlation lacks physiological meaning since it appears entirely attributable to covariation with the concomitant decrease in albumin in the course of pregnancy. Inasmuch as the changes in the fructosamine concentration with pregnancy are less than 5%, which approximates to the assay error (chapter 3), correction of the fructosamine concentration for gestational age as well as for albumin concentration in a clinical setting appears to unnecessary.

Glucose tolerance

With respect to glucose tolerance, theoretically, in pregnancy two opposite factors are operative which may influence both the fructosamine and HbA₁ concentrations. The 10% decrease observed in the fasting glucose concentration in the course of pregnancy is likely to have a lowering effect on the concentrations of both parameters. On the other hand, in the course of pregnancy the fructosamine and HbA₁ concentrations may rise as a result of a decrease of glucose tolerance towards term, as demonstrated by an increase in the glucose concentration 2 hours after glucose load by 24% and an increase in the area under the OGTT curve by 17%. Balance between these opposite effects may explain why fructosamine and HbA₁ concentrations in normal pregnancy change little.

In short, in the clinical setting both HbA₁ and fructosamine concentrations should be considered to vary independent of gestational age.

Chapter 7

The value of fructosamine measurement for the prediction of hyperglycaemia-related adverse neonatal outcome and large-for-gestational-age births

(Submitted for publication)

Summary part 1

Over a period of 18 months, 765 consecutive patients were studied to determine the ability of maternal serum fructosamine measurements to identify patients at risk for the sequelae of hyperglycaemia. The birth weight ratio (BWR) was higher (p < 0.05) in the offspring of patients in whom fructosamine concentrations in pregnancy had been higher than 2.30 mmol/l. In the offspring of these patients, the incidence of neonatal hypoglycaemia, hyperbilirubinaemia and respiratory distress syndrome was not increased. Although the BWR did vary as a function of the fructosamine concentration, only 1.4% of the variation in BWR was attributable to variation in the fructosamine concentration; this contribution was clearly lower than that of influences such as smoking (10%), and weights of the infant’s mother (6.5%) or father (2.8%). Receiver operating characteristic curves confirmed the limited screening value of fructosamine measurements for identifying patients who were to give birth to a large-for-gestational-age (LGA) infant. It is concluded that in an unselected population fructosamine measurement is an insensitive method for predicting neonatal complications of maternal hyperglycaemia and LGA births.
Summary part 2

A subpopulation of 175 patients from the original study sample was selected on the basis of clinical risk factors for gestational diabetes. The presence of these risk factors was reason to subject them to a 75 g oral glucose tolerance test (OGTT). In this selected population neither the fructosamine concentration alone, nor the combination of fructosamine concentration and OGTT outcome were sufficiently sensitive to identify patients whose offspring was destined to develop complications such as hypoglycaemia, hyperbilirubinaemia, or respiratory distress syndrome. The higher contribution of the fructosamine concentration to the variation in BWR in this subpopulation (5.8%) relative to that in the unselected population (1.4%) did not raise the independent screening value of fructosamine measurement for predicting LGA births. However, when fructosamine measurement was used in combination with the outcome of the OGTT, the predicting value for the subsequent birth of an LGA infant increased markedly.
Part 1

Introduction

For many years, diabetes mellitus antedating pregnancy has been recognized as an important cause of foetal death, birth defects, and increased neonatal morbidity. The infants of diabetic mothers are not only prone to macrosomia but show also a higher incidence of neonatal hypoglycaemia, respiratory distress syndrome (RDS) and hyperbilirubinaemia (Kitzmiller et al., 1978). Poor control of diabetes during pregnancy has often been held responsible for the increased incidence of these complications, whereas meticulous glucose control in pregnant diabetics is generally considered effective in reducing the risk of the neonatal sequelae of hyperglycaemia (Landon et al., 1987).

Gestational diabetics, in whom glucose intolerance is first detected during pregnancy, resemble pregnant diabetics with respect to pregnancy outcome. This is suggested by the higher incidence of macrosomia, neonatal hypoglycaemia, hyperbilirubinaemia and RDS in these patients (Gabbe et al., 1977). Moreover, it has been reported that the rate of large-for-gestational-age (LGA) infants in gestational diabetics may also be reduced by normalizing the mean blood glucose concentration (Langer and Mazze, 1988).

Measurement of the fructosamine concentration gives indirect information about the mean blood glucose concentration during the preceding 1-3 weeks (Hindle et al., 1986; Daubresse 1987). For management of both pregnant diabetics and gestational diabetics, the fructosamine measurement has been reported to provide useful information. In these patients, high fructosamine concentrations during pregnancy have been associated with macrosomia (Roberts and Baker, 1987; Roberts et al., 1988). However, the usefulness of fructosamine measurement as a screening test to identify pregnant women at risk of developing hyperglycaemia-related neonatal complications, has not yet been evaluated.

The present study was designed to assess the efficacy of fructosamine measurement during pregnancy for identifying patients at risk of the sequelae of hyperglycaemia. To this end, the relation between the fructosamine concentration during pregnancy and newborn weight was studied in a population with presumed low incidence of hyperglycaemia. In addition, the possible association between elevated fructosamine concentrations during pregnancy and increased incidences of neonatal hypoglycaemia, hyperbilirubinaemia or RDS was evaluated (part 1).

In a subpopulation with clinical signs or history suggesting an increased risk of glucose intolerance, the screening value of fructosamine measurement was compared
with that of the OGTT. Finally, in the latter population the predictive value of the combination of the two methods with respect to the sequelae of hyperglycaemia was determined (part 2).

Patients

During an eighteen month period ending in August 1988, all pregnant women (n = 893) presenting at the antenatal clinic or delivery room at the De Wever Hospital, Heerlen, were informed about the study and were invited to participate. In the 816 patients who agreed to do so, fructosamine was determined at least once during pregnancy. Patients with no first trimester ultrasound confirmation of their expected dates of confinement (n = 33) were excluded from the study as were patients with multiple pregnancy (n = 12). Also excluded from the study were pregnant diabetics (n = 6). The remaining 765 patients entered the study population. Table 7.1 lists some characteristics of these patients in comparison with a reference population, constituting a major fraction of those women who were delivered in hospital in The Netherlands in 1988. In this table it is illustrated that the incidence of preterm birth was considerably lower in the study population than in the reference population. This could be a result of selection, since the criteria for entering the study excluded patients with multiple pregnancy and pregnant diabetics, both of whom tend to be delivered prematurely.

Blood samples for fructosamine measurement were collected up to four times in each patient: in early pregnancy (before 16th week), mid-gestation (16-32 weeks), late pregnancy (after 32nd week), and 6 weeks post partum. The obstetricians were kept unaware of the results of the measurements.

Maternal age, ethnic origin, parity, height, and smoking were registered as were the fathers' heights and weights. Since only few patients could recall their pre-pregnancy weight, the first trimester weight (10 +/− 2 weeks) was considered 'reference' maternal non-pregnant weight. Body mass index was calculated by dividing weight in kilograms by the height in meters squared. Obesity was defined as a body mass index over 30 kg/m² (Garrow, 1981). Patients were only considered to have a family history of diabetes mellitus when at least one first degree relative had the disease. Weight gain in pregnancy was defined as the difference between the weight determined prior to delivery and that in the first trimester.

Preterm birth was defined as birth at a gestational age of less than 37 completed weeks. Instrumental delivery was defined as labour in which the foetus was extracted by forceps or vacuum. The infant's birth weight ratio (BWR) (%) was calculated by dividing its birth weight by the 50th weight centile for an infant of the same sex, gestational age, and parity, as reported by Kloosterman (1970). Infants were considered large-for-gestational-age (LGA) and small-for-gestational-age (SGA) when their BWRs were above 115% and below 81%, respectively. These values corresponded with the 90th and 10th percentile of the BWRs of our population. The capillary plasma glucose concentration was determined at least once in all infants admitted to the neonatal care unit as well as in all LGA infants (n = 320). A newborn was considered hypoglycaemic when its plasma glucose concentration was less than 2.0 mmol/l at least once during the first 72 hours. A newborn was considered hyperbilirubinaemic whenever treatment was required according to Brown's guidelines (1979). Requirement of continuous positive airway pressure or artificial ventilation during more than 24 hours was defined as respiratory distress syndrome (RDS). The incidence of congenital malformation in the tables refers to those emerging during the first week after delivery. Minor anomalies such as congenital dislocation of the hip, inguinal hernia and an undescended testicle were not included.

The population studied embodied 14 insulin-treated and 13 diet-treated gestational diabetics, detected by OGTT in patients with clinical risk factors. Gestational diabetes was classified according to the WHO criteria (WHO report, 1985). The study protocol was approved by the ethical committee of the hospital.
Analytical techniques

The techniques by which fructosamine and glucose were measured have been described in detail in chapter 4.

Statistical analysis

Data are presented as means with their standard deviation (SD) or means with their standard error of the mean (SEM). Comparisons between groups were performed by the Mann-Whitney U-test. Continuous variables divided over two groups were evaluated by Spearman's correlation test. The Chi-square test was applied to compare categorical data, expressed as frequencies. In case of small sample size, the Fisher exact probability test was employed. For the purpose of trend detection, the longitudinal and cross-sectional observations of fructosamine concentrations, determined in adjacent periods in pregnancy and post partum, were compared with Student's paired and unpaired t-test, respectively. The relationship between fructosamine and age was quantified by linear regression. A probability of less than 5% (p < 0.05) was considered significant. The ROC curve technique (Sackett et al., 1985; Richardson et al., 1985) was applied to determine the screening value of a given test per se and of a given test relative to alternative tests. Multiple linear regression analysis was used to determine the fractional contribution to the variation in BWR of various maternal characteristics including that of fructosamine concentrations.

Results

Fructosamine measurements

Table 7.2 lists the number of patients and mean fructosamine concentrations in each pregnancy period and post partum. The post-partum fructosamine concentration served as the non-pregnant value. The mean differences between consecutive periods are also shown in this table. The fructosamine concentration was lower in pregnancy than in the non-pregnant state, irrespective of gestational age, both within and in between subjects. Even the longitudinal analysis did not show a consistent change in the fructosamine concentration with pregnancy. The intra-individual variation in pregnancy was considerable as indicated by the large SD. This agrees with data reported recently by Staley and co-workers (1988).

Fructosamine measurement and prediction of LGA births

To evaluate the effect of gestational age on the value of fructosamine measurement to predict LGA births, ROC curves based on 3 periods of pregnancy were constructed (early-, mid-, late-pregnancy). This method allows evaluation of the value of the fructosamine measurement as a screening method for LGA births over the entire range of values. Moreover, the optimal measurement period in pregnancy and the optimal cut-off value can be derived. Figure 7.1 shows that in the population studied, fructosamine measurement had little value in predicting subsequent birth of an LGA infant, irrespective of the gestational period of measurement, as the ROC curves approached the 45-degree diagonal through the origin. Each point on this diagonal represents an equal likelihood of a true positive (sensitivity) and false positive (100-specificity) outcome as would occur by chance alone. The cut-off value 2.30 mmol/l in mid-pregnancy was found to provide the largest difference between true positive and false positive results with respect to the prediction of LGA births.

Comparison of patients with different fructosamine concentrations

In addition, the usefulness of fructosamine measurements for identifying pregnant women at risk of developing hyperglycaemia-related complications was evaluated by comparing patients with a 2nd or 3rd trimester fructosamine value above 2.30 mmol/l with those in whom this value was below this level. In 748 patients the fructosamine concentration was measured at least once after the 16th week of gestation. Because of the ROC curve patterns (figure 7.1) it was decided to chose the
Figure 7.1 Receiver operating characteristic curves of early, mid-, and late pregnancy fructosamine concentrations for predicting the subsequent birth of an LGA infant. Cut-off values (mmol/l) from left to right in the graph: 2.50; 2.40; 2.30; 2.20; 2.10; 2.00.

Figure 7.2 Relationship between maternal age and non-pregnant fructosamine concentration (mean ± SEM).
mid-pregnancy fructosamine value in the comparison unless only a late-pregnant value was available. The results are listed in table 7.3.

The maternal characteristics of the normal and high fructosamine groups were comparable, except for age. By linear regression analysis the following regression equation was calculated for the relationship between non-pregnant fructosamine levels (y; mmol/l) and maternal age (x; years):

\[ y = 0.0086x + 2.08 \ (n=291, \ r=0.20, \ p<0.001). \]

This relationship was determined for the age interval between 17 and 40 years and is illustrated in figure 7.2. The effect of age appeared to be at least in part responsible for the difference in fructosamine concentrations between the two groups listed in table 7.3.
The incidence of neonatal hypoglycaemia, hyperbilirubinaemia, RDS and malformations was very low in both fructosamine groups.

**Fructosamine concentration and birth weight ratio**

More than 70% of the fructosamine values after the 16th week were higher than 2.05 mmol/l. In this range the BWR was correlated with the fructosamine concentration (Spearman's correlation test, \( r = 0.13, \ p < 0.05 \); see figure 7.3).

![Figure 7.3 Relationship between birth weight ratio (BWR) and fructosamine concentration after the 16th week of pregnancy (mean ± SEM)](image)

To determine whether the apparently weak relationship between fructosamine concentration and BWR in this range was due to covariance with other variables, multiple linear regression analysis was employed to quantify the individual contribution to the variation in BWR of a number of independent variables with possible effect on foetal growth rate. These variables included maternal age and height, smoking habits, first trimester weight, first trimester diastolic blood pressure, first trimester haematocrit, as well as fructosamine concentration, father's weight and height. From these 9 variables, the following available parameters were selected by the regression: smoking, weight of the mother in early pregnancy, weight of the father, and fructosamine concentration after the 16th week of gestation. The results are listed in table 7.4. The analysis demonstrated that 10.0% of the variation in BWR was attributable to smoking, 6.5% to maternal weight, and 2.8% to the weight of the father. Variation in fructosamine concentration could only explain 1.4% of the

remaining variation in BWR. Although the effect was small, it was significant and not due to covariance with any of the other variables in the regression.

Discussion

Identification and treatment of hyperglycaemia during pregnancy has been advocated for many years in an attempt to reduce the unwanted sequelae normally found in the infant of the diabetic mother (Adashi et al., 1979). Screening all pregnant patients by random measurement of blood glucose concentration has been recommended by Lind and Anderson (1984), but has been proven inadequate in a population with a high prevalence of abnormal glucose tolerance (Nasrat et al., 1988). Screening pregnant patients by an OGTT on the basis of clinical risk factors will identify only 50% of all potentially hyperglycaemic patients (Lavin, 1985).

The decision to treat a patient with insulin or diet is determined in the first place by the patient's daily glucose profile in response to her own nutritional habits, irrespective of the result of the OGTT (Second International Workshop Conference on Gestational Diabetes, 1984). This implies that screening for hyperglycaemia can be considered more important than screening for an abnormal response to a non-physiological glucose load (OGTT). As the fructosamine concentration is an indirect estimate of mean blood glucose, its measurement was expected to provide an attractive alternative for identifying pregnant patients at risk of the sequelae of hyperglycaemia.

In this study we ignored the potential effect of insulin treatment (Cousan and Imarah, 1984) for two reasons. Firstly, the incidence of LGA births in the insulin-treated gestational diabetics (n = 14) was higher (29%) than in the total population (10%). Secondly, inadequate treatment would not only have resulted in a higher birth weight, but also in a higher fructosamine concentration (Roberts et al., 1988).
The incidence of neonatal hypoglycaemia, hyperbilirubinaemia and RDS was evenly distributed over both the high and normal fructosamine groups. It should be realized that in this study population such apparently rare neonatal complications may result from disorders other than maternal hyperglycaemia. For instance, neonatal hypoglycaemia may also result from reduced hepatic glycogen reserve (low birth weight infants) and increased metabolic needs (hypothermia and systemic infections). In the study population hypoglycaemia was diagnosed in only eight newborns, three of which were born preterm, three were SGA and only one was LGA.

The extent of maternal hyperglycaemia is established as one factor responsible for infant macrosomia via the foetal hyperglycaemia - foetal hyperinsulinism mechanism, originally proposed by Pedersen (1977). Therefore, pregnant women with previous delivery of a LGA infant are often screened for hyperglycaemia by an OGTT. If hyperglycaemia is the cause of excessive foetal growth, diet and insulin treatment should normalize foetal growth rate and thus diminish the risk of traumatic delivery (Coustan and Imarah, 1984). As compared to AGA (appropriate-for-gestational-age) and SGA infants, LGA infants have a higher risk of being delivered by forceps, vacuum or Caesarean section; this is supported by our experiences in the population studied (25% and 41%, respectively). However, it should be stressed that LGA birth (and BWR) is the resultant of several growth-stimulating and growth-inhibiting factors, among which excessive glucose supply to the foetus is only one. The fructosamine concentration will only be related to that part of (over)growth which is associated with maternal glucose supply to the foetus. In order to estimate the real contribution of the fructosamine concentration to the variation in BWR, we determined its independent effect on this parameter. Multiple linear regression analysis demonstrated that the fructosamine concentration could only explain a small fraction (1.4%) of the variation in BWR. In agreement with this finding was the weak correlation between BWR and the fructosamine concentration during pregnancy ($r = 0.08$, $p < 0.05$). This correlation may explain the small but significant difference in mean BWR between the high and normal fructosamine groups (table 7.3). These differences were too small to be associated with a higher incidence of instrumental delivery and/or Caesarean section in the high-fructosamine group.

The results of this study provide convincing evidence that fructosamine measurement has little predictive value when used as a screening test for identifying LGA infants in a low-risk population. This observation may be the consequence of a low fractional contribution of maternal hyperglycaemia to the rather mixed LGA target group. As a matter of fact, the latter group is only put together on the basis of neonatal weight, without taking into account the preceding foetal growth rate and the impact of genetic and environmental influences on size.

From this study it can be concluded that fructosamine measurement should be considered as an insensitive method for predicting adverse neonatal outcome and LGA

112
births caused by maternal hyperglycaemia. To determine whether this result is related to the low incidence of maternal hyperglycaemia or to the poor sensitivity of the test itself, we estimated the value of fructosamine in a population with a (presumed) higher incidence of hyperglycaemia. The results are given in the second part of this chapter.
Part 2

Introduction

In the first part of this study it was concluded that fructosamine measurement alone had little screening value when used in a low-risk population for identifying patients at risk of the sequelae of hyperglycaemia such as LGA births. This conclusion may not be valid for a high-risk population. In addition, the screening value of fructosamine may increase when the latter is evaluated in combination with some other potentially relevant variable such as the OGTT. We therefore decided to determine the value of fructosamine measurement as a screening test in a population in whom the risk of maternal hyperglycaemia was higher. Furthermore, we evaluated the value of fructosamine measurement as a test to screen for LGA births and, also, whether this screening value would increase when the result of the OGTT was taken into account.

Patients

The study sample consisted of a subgroup of 175 patients selected from the original study sample as described in part 1. In these patients an OGTT was performed during pregnancy on the basis of clinical risk factors for gestational diabetes. These factors included obesity, age over 30 years, suspected LGA foetus, a family history of diabetes mellitus, polyhydramnios, glycosuria and/or typical problems in the obstetrical history such as previous birth of an LGA infant, unexplained stillbirth, congenital anomalies and recurrent miscarriages. A 75 g OGTT was performed and interpreted according to WHO recommendations (1985) (Table 1.1). Patients with gestational diabetes mellitus and patients with gestational impaired glucose tolerance were both defined as gestational diabetics. During the eighteen-month study period 27 gestational diabetics were identified, most of them in the second half of pregnancy. After the diagnosis had been made, all gestational diabetics were given dietary instruction by a dietician. Caloric intake of 1800-2200 kcal per day was prescribed, distributed over carbohydrates (50%), protein (20%), and fat (30%). If dietary management did not result in fasting plasma glucose concentrations below 5.8 mmol/l and 2-hour postprandial plasma glucose levels below 7.5 mmol/l on two or more occasions within a two-week interval, insulin therapy was initiated (recommendations of the Second International Workshop-conference on Gestational Diabetes Mellitus (1985) and the World Health
Organization (1985)). According to these criteria, 13 gestational diabetics were treated with a diet only, whereas 14 patients required insulin supplementation.

Inherent to the selection procedure, in the OGTT subgroup a higher incidence of previous miscarriage, family history of diabetes, obesity, BWR, and LGA births was found than in the original study group (table 7.5). However, the incidence of neonatal morbidity did not differ between the two groups.

Blood sampling for fructosamine measurement was performed as described in part 1. To allow comparison of the value of fructosamine measurement with that of the OGTT and to be able to evaluate the combination of both tests, those fructosamine measurements were selected which were performed in the same period of gestation as the OGTT.

Analytical techniques and statistical analysis

Analytical techniques and statistical analysis have been detailed in part 1.
Results

*Prediction of hyperglycaemia-related adverse neonatal outcome and LGA births by fructosamine measurement*

To estimate the value of fructosamine measurement in this presumably high-risk population, patients with fructosamine concentrations above and below 2.30 mmol/l were compared with each other in the same way as in part 1. The results can be derived from table 7.6. Patients in the high fructosamine group (n = 37) were significantly older (p < 0.005) and seemed to be delivered more frequently of an LGA infant than patients in the normal fructosamine group (n = 138) (30% and 14%, respectively). However, the latter difference did not reach significance. The incidence of neonatal morbidity was similar in the two groups.

*Prediction of hyperglycaemia-related adverse neonatal outcome and LGA births by OGTT*

Patients in whom the OGTT was abnormal (n = 27) were older (p < 0.02) and more often obese (p < 0.05) than patients with a normal OGTT (n = 148). The incidence of LGA births (22% and 16%, respectively) and of delivery by forceps/vacuum/Caesarean section (18% and 32%, respectively) did not differ significantly between patients with abnormal or normal OGTT results. The incidence of neonatal complications such as hypoglycaemia, hyperbilirubinaemia and RDS was very low in the 175 patients of the population sample. The discriminating value of the OGTT with respect to these complications could therefore not be tested (table 7.6).

*Prediction of hyperglycaemia-related adverse neonatal outcome and LGA births by combining the fructosamine concentration with the outcome of the OGTT*

The selection based upon the fructosamine concentration can be combined with that based upon the OGTT. The results of various combinations of these two parameters are listed in table 7.6. With respect to the neonatal morbidity, no conclusions could be drawn since the incidence of neonatal morbidity was too low in all four groups. In patients with a normal OGTT, the fructosamine measurement did not increase the chance of identifying those women who were to give birth to an LGA infant or an infant with a higher BWR. However, in patients with an abnormal OGTT the BWR was higher and the predictive value with respect to the incidence of LGA births increased from 6% to 46% when the concomitant fructosamine value was higher instead of lower than 2.30 mmol/l.

* Mann-Whitney U test  
** Fisher's exact test

The screening value of fructosamine, the OGTT, and the combination of these two tests with respect to the subsequent birth of an LGA infant was also evaluated by the ROC-curve method. The ROC curve for the OGTT was constructed with the glucose concentration determined 2 hours after the glucose load. The ROC curve representing the combination of the tests described the screening value of fructosamine measurement in patients with an abnormal OGTT (2 hours glucose 7.8 mmol/l or higher). The curves depicted in figure 7.4 confirm that only the combination of the two tests has screening potential. However, merging of the two tests reduced the number of detectable LGA infants by 80%, from 30 to 6 patients. It was not possible to determine whether this reduction was a "purification" of the LGA subpopulation or an undesirable loss of a fraction of this subpopulation.

Figure 7.5 illustrates how a series of fructosamine concentrations predicts LGA births when the 2h OGTT glucose concentration is taken into account. This figure
Figure 7.4 Receiver operating characteristic curves of fructosamine, 2h glucose OGTT and the combination of fructosamine with an abnormal OGTT (2h glucose OGTT $\geq$ 7.8 mmol/l) for predicting LGA births
Cut-off values for the different methods from left to right in the graph:
Fructosamine (mmol/l): 2.50; 2.40; 2.30; 2.20; 2.10; 2.00.
2h glucose OGTT (mmol/l): 9.0; 7.8; 7.0; 6.0; 5.0; 4.0.

Figure 7.5 Prediction of LGA outcome at various levels of fructosamine and 2h glucose OGTT
allows evaluation of the contribution of the OGTT at different values for the 2 hours glucose. It is clear that increments in the 2 hours OGTT glucose concentration as well as in the fructosamine concentration are paralleled by a rise in LGA incidence over the entire range of tested values.

**Contribution of fructosamine concentration and 2h OGTT glucose concentration to the variation in birth weight ratio**

The relationship of BWR with fructosamine and 2h OGTT glucose concentrations was further studied by multiple linear regression analysis. By this method the independent contribution to the BWR of several relevant environmental influences in foetal growth, including fructosamine and 2h OGTT glucose, could be determined (see also part 1). The results are listed in table 7.7. The analysis demonstrated that of the variation in BWR in this population, 12.1% was attributable to smoking. In contrast to what was observed in the total population (table 7.4), the contribution of the weights of mother and father to the variation in BWR was not significant. This may be the result of the smaller sample size (69 vs 254 in total population). The variation in fructosamine concentrations could explain 5.8% of the variation in BWR, with no additional contribution from the 2h OGTT glucose concentration.

**Table 7.7 Multiple linear regression analysis with some environmental factors known to influence foetal growth including fructosamine and 2h OGTT glucose concentrations as independent variables, and BWR as the dependent variable (n = 69)**

**Discussion**

The screening value of fructosamine, of the OGTT, and of these two tests combined, for identifying patients at risk for the sequelae of hyperglycaemia, was evaluated in a selected high-risk population. The incidence of neonatal hypoglycaemia, hyperbilirubinaemia and RDS in this subpopulation was as low as in the original study sample. The low incidence of these neonatal complications - which are known
to occur more frequently in the offspring of hyperglycaemic mothers (Kitzmiller, 1978; Gabbe et al., 1977; Landon and Gabbe, 1985) - implies that it was not possible to discern a relationship with these neonatal complications. The low incidence of neonatal complications requires some further explanation. Neonatal hypoglycaemia, preferably in combination with an LGA birth, can be considered as the most certain sign of maternal hyperglycaemia during late pregnancy. In our original population neonatal hypoglycaemia was observed a total of eight times, with a high likelihood of preceding maternal hyperglycaemia (as suggested by the birth of an LGA infant) only in one occasion. If neonatal hypoglycaemia were indeed a major complication of gestational diabetes, a higher incidence in our high-risk population should have emerged. In fact, our approach to screening for gestational diabetes has been reported to be inadequate since at least 50% of our gestational diabetics may remain undetected (Lavin, 1985). On the other hand, none of the missed cases developed the typical neonatal complications, whereas only one of 78 LGA infants developed hypoglycaemia in the immediate post-partum period. The mother of this infant had a normal OGTT and a fructosamine above 2.30 mmol/l. It follows that even in our presumed high-risk population neonatal hypoglycaemia did not present itself as a major complication.

Although the incidence of the typical neonatal complications in the OGTT subgroup was as low as in the total population, 30 patients of this group gave birth to an LGA infant, which is almost twice as high as the rate in the total population (18% vs 10%). As has been discussed before, an LGA birth does not always reflect the presence of excessive transplacental glucose supply. By definition, LGA represents a 10% fraction of the biological spectrum of birth weights which, among others, includes macrosomia due to maternal hyperglycaemia. Nevertheless, it is generally accepted that excessive transplacental foetal glucose supply occurs more often in an LGA than in an AGA subgroup (Langer and Maczka, 1988). Thus, the higher incidence of LGA birth in our OGTT subgroup could indicate an increased fractional contribution of glucose-related overgrowth. Since both fructosamine measurement and OGTT outcome reflect different aspects of hyperglycaemia, we investigated the screening value for subsequent LGA births of each of these two parameters separately as well as the screening value of the two tests combined. In patients with an abnormal OGTT the incidence of LGA birth was no higher than in patients with a normal OGTT. The pattern of the 2h OGTT glucose ROC-curve shown in figure 7.4 suggests that diet and/or insulin therapy had little effect on the incidence of LGA birth. As there is no sudden increase of foetal overgrowth at the cut-off value of 7.8 mmol/l (Weiner, 1988) and since all patients with a glucose concentration above this value were treated, a possible growth regulating effect of diet and/or insulin should have resulted in a fall in the incidence of LGA birth around this cut-off value. The smooth pattern of the ROC-curve around the 7.8 mmol/l cut-off value makes such a presumed growth regulating effect of a diet and/or insulin in our population unlikely. However, in this respect it should be stressed that
the limited number of cases does not allow firm conclusions on this matter. The limited value of the OGTT for predicting LGA births is also supported by the lack of an independent contribution of the 2h OGTT glucose concentration to the variation in BWR, although a possible weak effect of the 2h OGTT glucose concentration in the regression may have remained undetected due to the limited number of patients in the OGTT subgroup. This is supported by the concomitant inability of both maternal weight and weight of the father to contribute to the variation in BWR.

Although the incidence of LGA birth seemed to be higher in patients with high fructosamine concentrations (>2.30 mmol/l) than in patients with normal fructosamine concentrations (30% and 14%, respectively), this difference was not significant. The limited value of fructosamine measurement for predicting LGA births is further supported by the ROC curve pattern. At any cut-off point for fructosamine, the value of fructosamine measurement for predicting LGA births was poor (figure 7.4). Apparently, in the high-risk group the four times higher contribution of the fructosamine concentration to the variation in BWR (5.8% vs 1.4%) did not raise the value of fructosamine measurement as a screening test for LGA infants.

Although both OGTT and fructosamine alone had low predictive values for identifying LGA infants, the value of the combination of the two tests was definitely better than that of each test separately. Gestational diabetics with fructosamine concentrations above 2.30 mmol/l were delivered 7 times more often of an LGA infant than those with fructosamine concentrations below 2.30 mmol/l. This could not be attributed to differences in treatment between the two groups since treatments with diet and insulin were evenly distributed over the two groups. The apparently good performance of the combination of OGTT and fructosamine is illustrated in figure 7.5 for a set of fructosamine and 2h OGTT glucose values as well as in figure 7.4 as a ROC curve for the subgroup of gestational diabetics. In spite of the fact that the latter curve was only based on the results of 6 LGA infants, the favourable pattern of the curve suggests that at least in these 6 patients foetal overgrowth was most likely caused by excessive glucose supply due to maternal hyperglycaemia. However, LGA birth alone is too crude to serve as solid proof of preceding excess transplacental glucose supply.

The small proportion of LGA infants, 6 of 30, which were picked up by using the result of the OGTT and fructosamine combined, may also be an indication of the low incidence of maternal hyperglycaemia which was severe enough to cause LGA birth. We have already expressed our surprise about finding such a low typical morbidity with our (presumably) inadequate screening practice. A low fractional contribution of maternal hyperglycaemia to the LGA subpopulation would confirm that the majority of the LGA newborns are large as a result of environmental, nutritional or genetic factors. Although the lack of a more sensitive indicator of excess glucose supply to the foetus complicates the discussion, the low incidence of hyperglycaemia-related neonatal morbidity supports the concept that until now the clinical need to identify patients with gestational diabetes in this particular population is questionable.
In summary, even in a presumed high-risk population, both fructosamine and OGTT evaluated as independent variables were insensitive in predicting either neonatal complications of maternal hyperglycaemia or LGA births. However, the combination of fructosamine concentration and outcome of an OGTT gave rise to an interesting increase in predictive value for subsequent birth of an LGA infant.

Chapter 8

Summary and conclusions

Ever since diabetes mellitus became treatable, control of therapy and course of the disease has been an important subject of study. As the disease is primarily characterized by glucose intolerance, the control parameter most widely accepted in clinical practice has been the intermittent evaluation of blood glucose concentration. However, both in healthy persons and in patients suffering from diabetes mellitus, glucose values may vary over a wide range throughout the day, particularly with respect to time and composition of meals. This implies that evaluation of the disease on the basis of blood glucose values alone is hampered; stringent standardization of glucose measurement conditions is necessary.

With the discovery that measurement of the glycated proteins could serve as an alternative to repeated glucose measurements, a method free of interference by short-term fluctuations in glucose concentration was evolved. The concentration of glycated proteins in the patient’s blood has been found to provide a reliable estimate of the average glucose concentration over the preceding weeks. In fact, the measurement of one of these glycated proteins, the glycated haemoglobin (HbA1), is nowadays commonly used in the monitoring of glycaemic control.

Several years ago, the measurement the glycated serum proteins also became interesting for the glycaemic control in diabetics, particularly with the introduction of the highly practicable ‘fructosamine assay’. HbA1 and fructosamine measurements were found to be complementary to each other rather than alternatives, a direct consequence of their different half-lives. The fructosamine concentration serves as an indirect estimate of the mean glucose concentration over a preceding period of 1-3 weeks, whereas the HbA1 concentration reflects the average glucose level over a period of 6-10 weeks.

The study described in this thesis was designed to evaluate the possibilities and limitations of fructosamine as an estimate of the glycaemic status in various clinical conditions. If appropriate, fructosamine data were compared with HbA1 values.

In chapter 1 a general introduction is given on the importance of glycaemic control and the methods employed for its assessment in both pregnant and non-pregnant subjects.

In chapter 2 the literature on non-enzymatic glycation of proteins is reviewed. In the first part of this chapter some chemical aspects of the non-enzymatic glycation of proteins are described. The second and third parts focus on non-enzymatic glycation of haemoglobin (HbA1) and non-enzymatic glycation of serum proteins. With
respect to the latter, extra emphasis is put upon its measurement by the fructosamine assay. In the last part of this chapter, the non-enzymatic glycation of proteins other than haemoglobin and serum proteins is discussed. It is stressed that enhanced non-enzymatic glycation may interfere with many physiological processes in the body, for instance through the accelerated formation of irreversible glycation end products in vessel walls. This phenomenon may play an important role in the pathogenesis of most long-term diabetic complications.

In chapter 3 the principles and characteristics of the fructosamine assay are evaluated. The intra- and inter-assay variations were very low. The fructosamine concentration of serum that had been stored at \(-20^\circ C\) for an extended period appeared to be stable for at least one year and its use as a (secondary) standard with proper matrix is recommended.

In 103 non-diabetic patients the relation between fructosamine and serum proteins was studied. The serum fructosamine concentration correlated with the albumin and total serum protein concentration. A decrease in albumin by 1 g/l was paralleled by a fall in the fructosamine concentration by 0.026 mmol/l. Because of the small adjustment (1% per gram albumin), correction of the fructosamine concentration is only recommended when the serum albumin concentration differs by more than 10 g/l from the reference value.

In addition, it was confirmed that the fructosamine concentration does not change in response to short-term glucose fluctuations, such as occur during the OGTT. Blood for fructosamine measurement can therefore be sampled irrespective of the time of previous meals.

For the purpose of evaluating quality of glycaemic control, the value of fructosamine measurement is compared with that of HbA\(_1\) in chapter 4. In 180 elderly non-insulin dependent diabetics (NIDDM) a correlation was found between the glucose concentration 2 hours after breakfast on the one hand, and fructosamine and HbA\(_1\) concentrations on the other. In this study, the fructosamine concentration correlated also with the HbA\(_1\) concentration. The correlation between fructosamine and the other two variables did not improve by correcting the fructosamine concentration for the albumin concentration. From these data and those reported in the literature reviewed it was concluded that in NIDDM subjects fructosamine measurement is an attractive alternative to HbA\(_1\) determination, particularly when glucose control is to be evaluated over a preceding period of up to 4 weeks.

In chapter 5 the value of fructosamine and HbA\(_1\) measurement as screening and diagnostic tests for impaired glucose tolerance, diabetes mellitus and gestational diabetes is described. Glucose tolerance was tested by 75 g OGTTs. In a group of 312 non-pregnant patients suspected of diabetes mellitus, the fructosamine and HbA\(_1\) concentrations were higher in patients with impaired glucose tolerance or diabetes mellitus than in patients whose glucose tolerance was normal. The value of fructo-
mine and HbA₁ measurements as screening tests for impaired glucose tolerance and diabetes mellitus could be demonstrated by receiver operating characteristic curves. However, the diagnostic value of these tests for impaired glucose tolerance or diabetes mellitus was disappointing.

In a group of 250 pregnant patients suspected of gestational diabetes, it was demonstrated that both fructosamine and HbA₁ measurements lacked screening and diagnostic power with respect to gestational diabetes.

The patterns in fructosamine and HbA₁ concentrations throughout pregnancy are reported in chapter 6. In 276 patients with a normal OGTT in pregnancy, a small but significant decrease in fructosamine was observed. This change appeared to be attributable to a concomitant decrease in the albumin concentration. When the fructosamine concentration was corrected for the albumin concentration, the fructosamine concentration varied independently of gestational age. The decrease of the fructosamine concentration during pregnancy was so small that correction for albumin concentration or gestational age in the clinical setting seemed trivial.

In the course of pregnancy the HbA₁ concentrations as measured by two different techniques varied independently of the gestational age. Apart from that, the HbA₁ concentrations measured by the chromatographic column method (Biorad) were systematically higher than those measured with the electrophoretic method (Corning).

It was demonstrated that glucose tolerance decreased during pregnancy, as indicated by an increase in the area under the OGTT-curve (+17%) and in the 2h OGTT glucose concentration (+24%). On the other hand, the fasting glucose concentration decreased by 10%. Balance between these two features with opposite effects on the concentration of glycated proteins may explain why fructosamine and HbA₁ concentrations in normal pregnancy change little.

In chapter 7 the value of fructosamine measurement in pregnancy for the prediction of hyperglycaemia-related adverse neonatal outcome and large-for-gestational-age (LGA) births is described. In 765 consecutive pregnant patients the birth weight ratio (BWR) was higher in the offspring of patients in whom fructosamine concentrations in pregnancy had been higher than 2.30 mmol/l. In the offspring of these patients the incidence of hypoglycaemia, hyperbilirubinaemia and respiratory distress syndrome was not increased.

Although the BWR did vary as a function of the fructosamine concentration, only 1.4% of the variation in BWR was attributable to variation in the fructosamine concentration; this contribution was clearly lower than that of influences such as smoking (10%), and weights of the infant’s mother (6.5%) and father (2.8%). Analysing the results by receiver operating characteristic curves confirmed the limited screening value of fructosamine measurements for identifying patients who were to give birth to an LGA infant. It is concluded that in an unselected population fructosamine measurement is an insensitive method for predicting neonatal complications of maternal hyperglycaemia and LGA births.
A subpopulation of 175 patients from the original study sample was selected on the basis of clinical risk factors for gestational diabetes. The presence of these risk factors was reason to subject these women to a 75 g oral glucose tolerance test (OGTT). In this selected population both the fructosamine concentration alone and the combination of fructosamine concentration and OGTT outcome had a poor screening value for patients whose offspring was destined to develop complications such as hypoglycaemia, hyperbilirubinaemia, or respiratory distress syndrome. The higher contribution of the fructosamine concentration to the variation in BWR in this subpopulation (5.8%) relative to that in the unselected population (1.4%) did not raise the independent screening value of the fructosamine measurement with respect to predicting LGA births. However, when fructosamine measurement was used in combination with the outcome of the OGTT, the predicting value for the subsequent birth of an LGA infant definitely increased.

In short, it is concluded that:

1. Fructosamine measurement is comparable to that of HbA1 with respect to monitoring the recent glycaemic status in NIDDM patients.
2. Fructosamine and/or HbA1 measurements have screening potential but no diagnostic value with respect to diabetes mellitus; the tests are insensitive as screening tests for gestational diabetes.
3. The fructosamine concentration increases the value of an OGTT for identifying pregnant patients with a higher likelihood of giving birth to an LGA infant.
Samenvatting en conclusies

Diabetes mellitus is een ziekte met als voornaamste kenmerk abnormale glucoseconcentraties in het bloed van de patiënt. Bepaling van de hoogte van de glucoseconcentratie is daarom een belangrijke maatstaf voor de beoordeling van de therapie en het verloop van de ziekte. Bij gezonde personen, maar vooral bij patiënten met diabetes mellitus kan de glucoseconcentratie binnen een kort tijdsbestek (uren) flink schommelen. Deze schommelingen zijn met name gerelateerd aan het tijdstip en de samenstelling van de maaltijden. Het glucosegehalte van het bloed is daarom alleen bruikbaar als parameter bij het beoordelen van behandeling en beloop van de ziekte als de meting ervan onder streng gestandaardiseerde condities plaatsvindt.

Met de ontdekking van de mogelijkheid om het gehalte van niet-enzymatisch geglyceerde eiwitten te gebruiken als maatstaf voor de gemiddelde glucoseconcentratie in de voorafgaande periode (weken), kwam een parameter voor glucoseregulatie ter beschikking die onafhankelijk is van kortdurende schommelingen van het glucosegehalte. Van de bepalingen van geglyceerde eiwitten is die van geglyceerd haemoglobine (HbA1c) als eerste praktisch toegepast. De HbA1c-bepaling wordt tegenwoordig veel gebruikt voor de beoordeling van de glucoseregulatie op langere termijn.

Sedert enkele jaren is er ook belangstelling voor de beoordeling van het gemiddelde glucosegehalte met behulp van de concentratie geglyceerde serumeiwitten, chemisch aangeduid als fructosamines. Hiermee kan de glucoseregulatie op middellange termijn worden beoordeeld. Deze methode werd des te meer populair toen het mogelijk werd het gehalte te bepalen met de geautomatiseerde, eenvoudige en goedkope "fructosaminetest". Omdat het fructosaminegehalte een maat is voor het gemiddelde glucoseconcentratie van de voorafgaande 1-3 weken en het HbA1c-gehalte een maat is voor de gemiddelde glucoseconcentratie van de voorafgaande 6-10 weken, kunnen de tests als complementair worden beschouwd.

Het onderzoek dat in dit proefschrift is beschreven had als doel de mogelijkheden en beperkingen van de fructosaminebepaling, als maat voor het gemiddelde glucosegehalte, te evalueren in verschillende klinische omstandigheden waar een veranderd glucosemetabolisme een rol speelt, zoals bij diabetes mellitus en bij verminderde glucosetolerantie tijdens de zwangerschap. De resultaten van de fructosaminebepalingen werden meestal vergeleken met die van HbA1c-metingen.

In hoofdstuk 1 wordt in een algemene inleiding het belang van glucoseregulering besproken bij zowel zwangers als niet-zwangeren. Tevens worden de methoden beschreven waarmee de glucoseregulatie geëvalueerd kan worden.

In hoofdstuk 2 wordt een overzicht gegeven van literatuur die betrekking heeft op niet-enzymatische glycerering van eiwitten. Na een korte bespreking van enkele chemische aspecten van de reactie tussen suikers en eiwitten wordt met name aandacht besteed aan de niet-enzymatische glycerering van haemoglobine en serumeiwitten.
Meer in het bijzonder wordt de bepaling van geglyceerde serumeiwitten met de fructosaminetest besproken. In het laatste deel van dit hoofdstuk wordt ingegaan op de niet-enzymatische glycering van andere eiwitten. Uit de literatuur blijkt dat toegenomen niet-enzymatische glycering van eiwitten door verhoogde glucoseconcentraties diverse fysiologische processen in het lichaam nadelig beïnvloedt en dat bijvoorbeeld in de vatenwand de vorming van irreversibele eindproducten van glycatie wordt versneld. Het leidt geen twijfel dat de niet-enzymatische glycatie van eiwitten centraal staat in de pathogenese van de meeste chronische complicaties van diabetes mellitus.

In hoofdstuk 3 worden eigen onderzoeken met betrekking tot het principe en de kenmerken van de fructosaminetest beschreven. De intra- en interrun variaties waren laag. Tevens bleek dat het fructosaminegehalte van diepgerekt serum gedaan tenminste een jaar stabiel was; bij –20°C bewaard zogenaamd ‘poolserum’ is daarom een goede (secundaire) bepalingsstandaard.

De invloed van het serumeiwitgehalte op de fructosaminevorming werd bij 103 niet-diabetische patiënten onderzocht. Het fructosaminegehalte bleek te correleren met zowel het albumine- als het totale serumeiwitgehalte. Een albumine daling van 1 g/l ging gepaard met een daling van het serumeiwitgehalte met 0.026 mmol/l. In de praktijk is correctie van het fructosaminegehalte voor de albumineconcentratie, in verband met de relatief kleine aanpassing (1% per gram albumineverschil) en het ermee invoeren van een nieuwe variabele met een extra bepalingsonnauwkeurigheid (albumine), alleen zinvol wanneer de albumineconcentratie meer dan 10 g/l van de referentiewaarde afwijkt.

Voorts werd bevestigd dat het fructosaminegehalte onafhankelijk is van snelle en soms sterke variaties van de glucoseconcentratie zoals die optreden na glucosebelasting bij een orale glucosetolerantie test (OGTT). Bloed voor de fructosaminemeting kan daarom, in tegenstelling tot bloed voor glucosebepaling (en sommige HbA₁c-bepalingen), onafhankelijk van het tijdspan van de maaltijd worden afgenomen; analyseresultaten worden niet erdoor beïnvloed.

De waarde van de fructosaminemeting als parameter voor de controle van de glucoseregulering wordt in hoofdstuk 4 vergeleken met die van de HbA₁c-bepaling. Bij 180 patiënten met niet-insuline-afhankelijke diabetes mellitus werd een goede correlatie gevonden tussen de glucoseconcentratie 2 uur na het ontbijt enerzijds, en het fructosamine- en HbA₁c-gehalte anderzijds. De fructosamine- en HbA₁c-gehalten waren ook met elkaar gecorreleerd. De mate van correlatie werd niet versterkt door correctie van het fructosaminegehalte voor de albumineconcentratie. Aan de hand van deze resultaten en gegevens uit de literatuur wordt geconcludeerd dat voor de controle van de glucoseregulering gedurende de aan de bloedafname voorafgaande 4 weken, het fructosaminegehalte een goed alternatief is voor het HbA₁c-gehalte bij patiënten met niet-insuline-afhankelijke diabetes mellitus.
De waarde van de fructosamine- en HbA₁c-meting als screenings- en diagnostische test voor verminderde glucose tolerantie, diabetes mellitus en zwangerschapsdiabetes werd onderzocht en beschreven in hoofdstuk 5. Bij een groep van 312 patiënten, verdacht van diabetes mellitus, werd de 75 g OGTT (WHO criteria) gebruikt als standaard-test voor de bepaling van de glucose tolerantie. Bij patiënten met verminderde glucose tolerantie of diabetes mellitus werd een significant hoger fructosamine- en HbA₁c-gehalte gevonden dan bij patiënten met een normale glucose tolerantie. Door analyse van de gegevens met “receiver operating characteristic curves” kon worden aangetoond dat de fructosamine- en HbA₁c-bepaling een zekere screeningswaarde hebben voor verminderde glucose tolerantie en diabetes mellitus. De tests bleken echter ongeschikt te zijn als diagnostische methoden voor verminderde glucose tolerantie of diabetes mellitus.

Bij een groep van 250 zwangere patiënten bleek noch de fructosamine- noch de HbA₁c-bepaling van waarde te zijn als screenings- of diagnostische test voor zwangerschapsdiabetes. Bij deze conclusies speelt uiteraard ook de soms niet eenduidige uitslag van de OGTT een rol.

In hoofdstuk 6 wordt de invloed van de zwangerschap op het fructosamine- en HbA₁c-gehalte beschreven. In een groep van 276 patiënten met een normale OGTT werd in het verloop van de zwangerschap een kleine doch significante daling gevonden van het fructosaminegehalte. Deze verandering kon verklaard worden door de met haemodilutie gepaard gaande daling van het albuminegehalte tijdens de zwangerschap. Na correctie van het fructosaminegehalte voor het albuminegehalte bleek het (gecorrigeerde) fructosaminegehalte niet meer significant te veranderen met de zwangerschapsduur. Overigens was de daling van het fructosaminegehalte tijdens de zwangerschap zo klein, dat correctie voor zwangerschapsduur of albuminegehalte in de dagelijkse praktijk van de klinische geneeskunde overbodig is.

Het HbA₁c-gehalte, gemeten met twee verschillende methoden, veranderde niet in het verloop van de zwangerschap. Wel waren de HbA₁c-gehalten die bepaald werden met een chromatografische kolommethode (BioRad) steeds hoger dan die welke gemeten werden met een electrophoretische methode (Corning).

In het verloop van de zwangerschap bleek er een daling op te treden van de glucose tolerantie, gemeten aan een toename van de oppervlakte onder de OGTT curve met 17% en een stijging van de 2-uurs glucosewaarde van de OGTT met 24%. Daarentegen daalde de nachtere glucosewaarde met 10%. Tijdens de normale zwangerschap zal een evenwicht tussen deze twee mechanismen, die een tegengesteld effect hebben op de gemiddelde glucose concentratie, resulteren in stabiele fructosamine- en HbA₁c-gehalten.

Voorts werd onderzoek verricht naar de waarde van de fructosaminebepaling in de zwangerschap voor het opsporen van patiënten van wie de pasgeborenen complicaties krijgen die gerelateerd zijn aan verhoogde glucosespiegels bij de moeder. De resultaten zijn vermeld in hoofdstuk 7. In een populatie van 765 zwangere bleek de
“birth weight ratio” (BWR, relatieve geboortegewicht) significant hoger te zijn bij pasgeboren van patiënten met een fructosaminegehalte in de zwangerschap boven 2.30 mmol/l. De incidentie van hypoglycaemie, hyperbilirubinaemie en het respiratory distress syndroom was bij de pasgeboren van deze patiënten niet verhoogd. Ondanks het feit dat de BWR varieerde met het fructosaminegehalte, kon slechts 1.4% van de variatie in BWR verklaard worden door variatie in de fructosamine-concentratie. Veel groter was de invloed van roken door de moeder op de variatie in BWR (10%). Ook het gewicht van de moeder (6.5%) en vader (2.8%) van het kind droegen bij tot de variatie in BWR. De beperkte waarde van de fructosaminbepaling voor het vroegtijdig opsporen van zwangeren die een kind met een overgewicht zouden krijgen, werd bevestigd door analyse van de gegevens met “receiver operating characteristic curves”. Geconcludeerd wordt dat de fructosaminbepaling in een niet-geselecteerde populatie een te ongevoelige methode is om overgewicht en/of complicaties bij de pasgeborene te voorspellen die het gevolg kunnen zijn van verhoogde glucosespiegels bij de moeder.

Nader onderzoek werd nog gedaan bij 175 patiënten uit de oorspronkelijke populatie van 765 zwangeren. Zij werden geselecteerd op basis van klinische risico-factoren voor zwangerschapsdiabetes en bij hen werd een OGTT verricht. In deze geselecteerde populatie bleek het niet mogelijk op basis van het fructosaminegehalte alleen, noch met de combinatie van fructosaminegehalte en resultaat van de OGTT patiënten op te sporen waarvan de pasgeboren hypoglycaemie, hyperbilirubinaemie of het respiratory distress syndroom ontwikkelden. Ondanks een hogere bijdrage van het fructosaminegehalte tot de variatie in de BWR in deze subpopulatie (5.8%) vergeleken met de bijdrage in de oorspronkelijke populatie (1.4%), verbeterde de voorspellende waarde van de fructosaminbepaling voor de geboorte van een kind met overgewicht niet. Echter bij combinatie van het fructosaminegehalte met het resultaat van de OGTT bleek de voorspellende waarde voor de latere geboorte van een kind met overgewicht duidelijk toe te nemen.

Samenvattend wordt het volgende geconcludeerd:

1. Voor de controle van de glucoseregulering gedurende de voorafgaande 4 weken bij patiënten met niet-insuline-afhankelijke diabetes mellitus is de waarde van de fructosaminbepaling gelijk aan die van HbA₁c.
2. De fructosamine- en/of HbA₁c-bepaling hebben wel screeningswaarde doch geen diagnostische waarde voor diabetes mellitus; de tests hebben geen screeningswaarde voor zwangerschapsdiabetes.
3. Het fructosaminegehalte tijdens de zwangerschap verhoogt de voorspellende waarde van de OGTT met betrekking tot de geboorte van een kind met overgewicht (LGA).
