Voorwoord

Het is meer dan een goede gewoonte en tegelijkertijd onmogelijk om allen die hebben meegewerkt aan het tot stand komen van dit proefschrift bij deze gelegenheid te noemen en naar behoren te bedanken. Allereerst moeten genoemd worden Dr L.A. Schellekens en Prof. Dr J. de Haan die beiden een belangrijk aandeel hadden in mijn opleiding tot vrouwenarts en mij op een overigens zeer verschillende manier hebben gestimuleerd tot het doen van onderzoek en het schrijven van een proefschrift. Dr J.L.H. Evers en Dr P.X.J.M. Bouckaert stonden aan de basis van respectievelijk het dierenexperimentele en het humane gedeelte van de studie en hebben nauwkeurig, met uitzonderlijke inzet en zeer vasthoudend het verloop ervan begeleid en gestuurd. Bijzondere dank gaat uit naar Drs M.G.R. Hendrix die het macrofagenonderzoek voor zijn rekening nam.

Dr E.J.P. Brommer en Dr J.W.J. van Wersch gaven waardevolle aanwijzingen bij het verwerken van de gegevens van de intra-abdominale fibrinolyse. Van de ervaring van Dr J.A. Land met het konijnemodel werd dankbaar gebruik gemaakt. Haar kritische houding ten aanzien van onderzoek en verslaglegging was een stimulans om het manuscript af te ronden.

Overigens heb ik ondervonden dat ook een thuisfront op 200 kilometer afstand bij het schrijven van een proefschrift een steun en toeverlaat kan zijn.

Ik dank U allen zeer.                        Maastricht, april 1988
Chapter 1

Introduction

Endometriosis may be defined as a disease characterized by the presence of functional endometrial glands and stroma in ectopic locations outside the uterine cavity. The ectopic endometrial tissue responds to ovarian steroids in a way similar to eutopic endometrium. Endometriosis is linked to the reproductive years, it does not occur in premenarcheal girls and it is believed to regress in the postmenopausal years. Patients with endometriosis usually present with either pelvic pain or infertility. The cyclic changes lead to the macroscopic features of the endometriotic lesions on the peritoneum and the ovaries as seen by laparoscopy. By accumulation of menstrual debris an ovarian lesion may become cystic. It is then called an endometrioma. Adhesions secondary to repeated rupture and sealing of endometriomata, should be considered part of the disease. The microscopic diagnosis asks for the presence of endometrial glands surrounded by endometrial stroma.

The first histological description of a lesion consistent with endometriosis was given by Von Rokitansky in 1860, who described small tumors on the wall of the Fallopian tube as adenomyomata (Ridley, 1968). The term "Endometriosis" was first used by Sampson in 1921. Since the classic papers of Sampson on the pathogenesis of endometriosis (Sampson, 1921, 1927, 1940), an overwhelming number of scientific articles has been published on the various problems encountered in this disease. Nevertheless, despite extensive basic and clinical research, endometriosis remains a disease without precise definition, it has an obscure pathogenesis and etiology, an extremely variable clinical presentation, an unpredictable course, and, except for surgical or physiological menopause, no known cure. Endometriosis tends to recur regardless of the treatment given.

In the first part of the following chapter (2.1) the pertinent literature on pathogenesis and etiology, classification, epidemiology, symptomatology, diagnosis, management and recurrence will be reviewed.

Endometriosis is usually described and studied as a histological entity, rather than a pathophysiological process. The pathophysiology of the endometriotic lesions may shed light on the association between endometriosis and infertility. Changes in the endometriotic lesions secondary to ovarian steroids may alter the intraabdominal environment, in which the early events of reproduction take place. These functional changes are possibly reflected in the peritoneal fluid bathing the reproductive organs in the pelvic cavity. In the second part of the following chapter (2.2 and 2.3) the literature is reviewed and discussed as it pertains to the relation
between endometriosis and infertility and to the changes that take place in the peritoneal fluid secondary to endometriosis.

Endometriosis has to be considered as a uniquely human condition. Basic research in the different aspects of the disease would require unacceptable human experiments. Therefore various animal models of endometriosis have been used to unravel problems that cannot be solved by research in human subjects. The third part of chapter 2 (2.4) comprises a review of the literature on animal research in endometriosis.

Chapter 2

Review of the literature

2.1 Endometriosis

2.1.1 Pathogenesis and etiology

Pathogenesis
Several theories have been developed to explain the pathogenesis of endometriosis. These theories, some of which have historical interest only, can be grouped in three categories as shown in Table 2.1 (Ridley, 1968). According to the hypothesis of coelomic metaplasia (Meyer, 1919), endometriosis arises as a result of metaplasia of the peritoneal serosa. These metaplastic changes occur secondary to inflammatory processes (Meyer, 1919) or hormonal influences (Novak, 1931). The capacity of the peritoneal serosa to undergo various forms of Müllerian metaplasia has been demonstrated by Lauchlan (1972). Elements of tubal and endocervical mucosa are seen next to endometrial epithelium (Lauchlan, 1966; Schwepppe, 1984b). There are several problems with the concept of metaplasia. Endometriosis only occurs if endometrium is present. In the few cases that were described in patients with Müllerian agenesis, (Rosenfeld and Lecher, 1981; Kühn et al., 1981) or 46,XY gonadal dysgenesis (Doty et al., 1980) the presence of en-

dometrial or tubal tissue has not been ruled out completely. Furthermore, the disease is not present in males. Three cases of endometriosis have been described in males (Oliker and Harris, 1971; Pinkert et al., 1979; Schrod et al., 1980). In these cases hypertrophy of remnants of the Müllerian ducts in the prostate, the utricle, developed after high-dose estrogen treatment. It is incorrect to call this endometriosis.

The induction theory (Levander and Normann, 1955; Merrill, 1966) is based on the assumption that substances, released by the uterine endometrium and transported by blood and lymph streams, induce the formation of endometriosis in different parts of the body. Levander and Normann (1955) implanted fresh and denaturated endometrium in the abdominal cavity of the rabbit. Histological observations were made daily for 7 days. They observed degeneration of the implant during the first four days, with cyst formation and epithelial differentiation characteristic of endometrium in the surrounding connective tissue during the next three days. Better results were obtained if the tissue was degraded before implantation. They concluded that dying endometrial tissue liberated specific substances activating undifferentiated mesenchyme to form endometrium. They found no evidence that living endometrial cells can grow out from an implant and establish cyst formation in the environment. On the other hand, both reactive granulation tissue in all its forms and true epithelial tissue arose as the result of different stimuli from the implants. Bernhard (1959) implanted decidual tissue, devitalized by trypan blue, subcutaneously in rabbits. In all implantation sites endometriosis developed. Merrill (1966) implanted viable and ischemic endometrial tissue within millipore filters intraperitoneally in the rabbit. The pore size of the filters was such that only chemical substances but no cells could pass. Endometrium-like epithelium and glands were observed in the connective tissue adjacent to the implants, suggesting that endometrium was capable to induce endometrial metaplasia. Since no endometrial stroma was found in the surrounding tissue, these changes do not meet the criteria for the definition of endometriosis.

The concept of endometriosis as a transplantation phenomenon involves different routes of dissemination. Iatrogenic, lymphogenic and hematogenic spread account for rare, extraperitoneal, locations of endometriosis (Javert, 1949, 1952; Scott et al., 1958; Dilts et al., 1965; Ridley, 1968; Hajdu and Koss, 1970; Hibbard et al., 1981). A more obvious route of dissemination is by the Fallopian tubes. According to the theory of implantation by retrograde menstruation endometriosis is a consequence of reflux of endometrial fragments through the Fallopian tubes during menstruation with subsequent implantation and growth on and into the peritoneum and the ovary (Sampson, 1921, 1940). The reflux implantation theory is based on the assumption that retrograde menstruation takes place and that viable endometrial cells reach the abdominal cavity and implant. Sampson based his theory largely on clinical and anatomical observations rather than on experimental evidence.

Goodall (1943) observed spill of blood in about 50% of laparotomies performed during menstruation. Blumenkrantz et al. (1981) reported that nine of eleven women
undergoing peritoneal dialysis had blood in the dialysate during their menstrual period. Halme et al. (1984a) obtained peritoneal fluid by laparoscopy in the perimenstrual period. Blood was found in 90% of the patients with patent tubes. If the Fallopian tubes were occluded only 15% had evidence of blood in the pelvis. Retrograde spillage of menstrual blood was observed in 76% of women laparoscoped for sterilization during menses by Liu and Hitchcock (1986). The viability of cast-off endometrial cells was proven by Keettel and Stein (1951). Willemsen et al. (1985) cultured uterotubal flushings obtained in the proliferative phase of the cycle. The capacity of the epithelial cells to proliferate in vitro was demonstrated, supporting the seeding theory of Sampson. A difference exists, however, between retrograde menstruation and flushings of uterus and tubes in the proliferative phase of the cycle.

Te Linde and Scott (1950) reported that endometriosis developed in monkeys with artificial uterine fistulas. They showed that menstrually discharged endometrial fragments had the capacity to implant in the abdominal cavity, although the theory that endometrial particles travel through the tubes and implant in the peritoneum was not confirmed by their experiment. A comparable case of endometriosis was reported in the human by Szlachtier et al. (1980) secondary to the Estes procedure. Ridley and Edwards (1958) collected menstrual blood during the first 24 hours of menstrual flow and implanted these elements into the abdominal wall superficial to the fascia in women scheduled for laparotomy at a later stage for other gynecologic indications. In two patients endometriosis was demonstrated after three and six months. They concluded that the desquamated endometrial cells were viable and capable of establishing endometriosis in ectopic sites. Again, this did not prove the reflux implantation theory. The high prevalence of endometriosis in girls with congenital obstruction of the menstrual outflow tract supports the theory (Hamon et al., 1966; Schifrin et al., 1973; Goldstein et al., 1980; Baker et al., 1982; Sanfilippo et al., 1986). Jenkins et al. (1986) assessed the anatomic distribution of endometriosis by a laparoscopic study of the location of implants, adhesions and uterine position. They concluded that the anatomical distribution of the endometrial implants, governed by the effects of gravity and the proximity to the site of abdominal entry, lends support to the theory of transplantation by retrograde menstruation. The possibility of a factor in the menstrual debris inducing metaplasia can not be excluded by their findings.

In summary, not all locations of endometriosis can be explained by one single theory. The reflux implantation theory of Sampson (1940) is supported by the distribution of the lesions in the abdominal cavity (Jenkins et al., 1986), the demonstration of the viability of shed menstrual endometrium in tissue culture (Keettel and Stein, 1951), the high prevalence of pelvic endometriosis in girls with congenital menstrual outflow obstruction (Sanfilippo, 1986) and animal experiments in which endometriosis was induced by the creation of uteropelvic fistulas (Te Linde and Scott, 1950). The theory of endometrial metaplasia of the peritoneal serosa is not contradictory, but may be supplementary (Levander and Normann, 1955; Bernhard, 1959). En-
Endometrial cells may stimulate metaplasia after they have been transported to a susceptible tissue. The difference between the implantation and induction theories may be characterized by the statement that the former seeks the origin of endometriosis on the cellular, and the latter on the molecular level (Levander and Normann, 1955).

**Etiology**

Retrograde menstruation is seen in the majority of women, with and without endometriotic lesions (Halme et al., 1984a). Endometrial cells can be found in the peritoneal fluid in patients with and without endometriosis (Konincx et al., 1980d; Willemsen et al., 1985; Bartosik et al., 1986). It remains unclear why not all women develop endometriosis. Likewise, the theory of in situ development offers an explanation of the pathogenesis of endometriosis, whereas the factors that initiate the ectopic growth are not known. Mechanical, hormonal, inflammatory, immunological and genetic factors may affect the etiology of endometriosis.

**Etiology, mechanical factors**

There are three possible routes of egress of menstrual outflow, the cervix and both Fallopian tubes. Changes in the anatomy of the genital tract, whether congenital or acquired, that impede menstrual outflow are considered to be an etiological factor in endometriosis (Fallas, 1956; Derryberry, 1966; Hanton et al., 1966; Schifrin et al., 1973; Goldstein et al., 1980; Baker et al., 1982; Olive and Henderson, 1987). Sanfilippo et al. (1986) reported on three patients with a uterus didelphys with unilateral imperforate vagina with extensive endometriosis. After creating a vaginal window into the blind pouch the endometriosis regressed. Changes in the genital tract that predispose to menstrual reflux have been described in women with maternal dethylostilbestrol (DES) exposure. Although the prevalence of endometriosis and cervical stenosis appears to be high in infertile women exposed to DES, a significant association could not be established (Stillman and Miller, 1984). Treatment of ectropion by cautery, cryotherapy or CO₂ laser, if carried out too far into the cervical canal can result in stenosis above the external os, with obstruction of natural drainage and subsequent potential retrograde menstruation (Raney, 1980).

Ayers et al. (1985) investigated possible anatomic-mechanical predispositions for increased endometrial backflow. During laparoscopy transcervical pressure profiles were obtained of the uterotubal junction. From the results obtained, they concluded that pelvic endometriosis was associated with significant uterotubal hypotonia when compared to normal controls or non-endometriosis infertility patients. They hypothesized that this hypotonia could predispose to retrograde menstruation. Along the same line Bartosik et al. (1986) showed, by flushing the Fallopian tubes, that endometrial cells were refluxed more often into the peritoneal cavity of women with endometriosis than in those of the control group, suggesting a deficient uterotubal control mechanism in patients destined to acquire endometriosis. The result of this study indicated that endometrial tissue can be flushed through the Fal-
opian tubes. The relevance of these findings remains to be established where spontaneous retrograde menstruation is seen in the majority of women.

In short, changes in the genital tract that favor menstrual reflux either congenital or secondary to surgical manipulation are predisposing factors for the development of endometriosis. The volume of regurgitated menstrual debris is probably important (Olive and Henderson, 1987). Women with short cycle lengths and menses for a week or longer have been reported to have greater than twice the risk of developing endometriosis. The risk for endometriosis may relate to menstrual factors that predispose to greater pelvic contamination with menstrual products (Cramer et al., 1986).

**Etiology, hormonal factors**

Endometriosis is a disease of the reproductive years. It is nonexistent in premenarcheal years, while menopause and castration lead to regression of the lesions. The influence of hormones on the development of endometriosis has been postulated by Novak (1931). Cyclic ovarian hormone secretion seems necessary for the growth or proliferation of ectopic endometrial tissue. The existence of hormonal modulation of endometriosis is supported by the presence of estrogen and progesterone receptors in endometriotic lesions (Tamaya et al., 1979; Jänne et al., 1981; Gould et al., 1983; Vierikko et al., 1985). Binns and Banerjee (1983) documented a case of endometriosis in a patient with Turner's syndrome that developed after 10 years of estrogen treatment. The view that estrogens and progesterone have an effect on the development of endometriosis was supported by Meigs (1960). He found more patients with endometriosis among women, who postponed childbearing to a later age. He postulated that continuous action of the ovarian hormones for years in a row, without pregnancies, causes endometriosis.

A distinction should be made between the influence of hormones in initiating and in maintaining endometriosis. The initiation of growth of endometriosis in the monkey has been proven to be independent of estrogens (Scott and Wharton, 1957; DiZerega et al., 1980). Scott and Wharton (1957) showed that the best growth of endometrial implants in castrated monkeys was achieved when they were treated with constant estrogen and intermittent progesterone administration. For maintenance of long-term viability of endometrial implants either estradiol or progesterone, alone or in combination, was required (DiZerega et al., 1980). It should be kept in mind that these studies of the influence of estrogens and progesterone were performed in an animal model with surgically implanted endometrium.

Brosens et al. (1978) found a lower concentration of estradiol and progesterone in the peritoneal fluid of patients with endometriosis, compared to patients without the disease. This lower hormonal content was accompanied by a higher number of luteinized unruptured follicles in endometriosis patients. They hypothesized that the lower concentration of progesterone allows proliferation and implantation of endometrial cells (Koningckx et al., 1980c).
Etiology, inflammatory factors

Sampson (1927b) postulated that the regurgitated menstrual blood acts as an irritant to the peritoneal surfaces and thus facilitates implantation. Obitsu (1980) and Malick (1982) hypothesized that a change in intraabdominal fibrinolysis could play an etiological role in the development of endometriosis and the adhesions seen in this disease. They observed a decreased fibrinolytic activity of the mesothelial cells lining the peritoneal cavity in patients with endometriosis. The fibrin exudate developing as a consequence of peritoneal damage by retrograde menstruation combined with the decreased fibrinolytic activity might lead to adhesion formation. In these adhesions endometrial cells might easily implant. Batzofin et al. (1985) measured peritoneal fluid fibrinolytic activity in patients with and without endometriosis. They could not detect differences and concluded that, if altered fibrinolysis plays a role in the etiology of endometriosis, these differences possibly can be found on tissue level rather than in the peritoneal fluid.

Etiology, immunological factors

Dmowski et al. (1981) studied the cell-mediated immune response to autologous endometrial antigens in monkeys with spontaneous endometriosis. They found a decrease in the cell-mediated immune response, although the monkeys were overall immunologically competent. They suggested that endometrial cells, after transtubal migration to the peritoneal cavity, only implant in women with a specific alteration in cell-mediated immunity. Steele et al. (1984) studied general and specific immune function in women with endometriosis. Nonspecific parameters of the immune system were the same in patients with and without endometriosis. Both lymphocyte stimulation, the afferent limb of cellular immunity, and cytotoxicity, the predominant efferent mechanism, were evaluated. The stimulation by autologous endometrial antigen of lymphocytes was reduced. The specific immune response, T-lymphocyte-mediated cytotoxicity to autologous endometrial cells was significantly reduced, suggesting an immunological basis for development of endometriosis. Specific cellular mechanisms aimed at limiting ectopic growth of the endometrial tissue were supposedly impaired in women with endometriosis. The degree of this impairment seemed to be directly related to the severity of the disease. Startseva (1980) reported reduced T-cell immunity and an increase in B-cell reactivity in women with endometriosis, indicating that both cell-mediated and humoral immunity are altered in endometriosis. Weed and Arquembourg (1980) detected C3 and IgG deposits in the uterine endometrium in patients with endometriosis and suggested an alteration in humoral immunity. Wood et al. (1983) reported that in Rhesus monkeys after total body exposure to proton irradiation the prevalence of endometriosis more than doubled compared to normal controls. They suggested that suppression of the immune system facilitated the development of endometriosis. Gleicher et al. (1984) studied the relative number of the effector cells of cell-mediated immunity, the different types of lymphocytes, in the peripheral blood of patients with endometriosis. No difference was found in relative numbers of T-, helper T-, suppressor T- and
B-lymphocytes in the peripheral blood of patients with endometriosis compared to patients without the disease. They stated that immune function is, however, only partially dependent on cell counts, and, probably more so, on the level of function of individual cell populations. In contrast to these authors Badawy et al. (1987) reported increased numbers of T- and B-lymphocytes in the peripheral blood and peritoneal fluid of patients with endometriosis compared to controls. Furthermore, the ratio helper T-suppressor T-lymphocytes was significantly increased in patients with endometriosis. They suggested that these results lend support to the concept of cell-mediated autoimmune reactions in endometriosis.

Olive and Henderson (1987) combined the theories of retrograde flow and altered cell-mediated lymphocyte cytotoxicity. They suggested that endometriosis develops in women with either an increased retrograde menstruation secondary to outflow obstruction, or an inability to remove the debris. These observations suggest that the immune system, humoral and cell-mediated, is at least altered in patients with endometriosis. Implantation or rejection of endometrial cells arriving in the abdominal cavity through the Fallopian tubes may be controlled by the cell-mediated immune system. Specific defects in the cell-mediated immunity would allow implantation of endometrial cells.

**Etiology, genetical factors**

A hereditary tendency to develop endometriosis has been reported (Henriksen, 1953; Frey, 1957; Van der Velden, 1961). Simpson et al. (1980b) showed a significantly higher prevalence of endometriosis in first degree relatives of patients with endometriosis than in a similar group related to their husbands. Of 123 patients with endometriosis, 5.8% of female sibs and 8.1% of mothers were similarly affected. Only 1% of the husbands' female sibs and only 0.9% of the husbands' mothers had endometriosis. From their results they calculated that a first degree relative of a patient with endometriosis has a chance of 7% to develop the disease. Polygenic/multifactorial inheritance seemed to them the most likely genetical etiology. Their results were confirmed by Lamb et al. (1986).

Steele et al. (1984) performed HLA-A and HLA-B typing of patients with endometriosis to examine the possibility of a link between these antigens and the disease. No increase nor decrease of particular antigens was observed. From these findings they concluded that further evidence of the multifactorial mode of inheritance was offered.

Simpson et al. (1984) studied 53 patients with endometriosis. There was no association between any HLA antigen (A, B, C, DR) and endometriosis. They concluded that HLA determinations are unlikely to detect endometriosis in relatives at increased risk.

Moen et al. (1984) typed 100 patients for HLA-A, -B and -C, and 24 also for HLA-DR. No significant deviations from the the antigen frequencies in a normal population were found. They concluded that the development of endometriosis does not seem to be associated with HLA-A, -B, -C or -DR antigens.
2.1.2 Classification

Classification of endometriosis is based on direct observation of the lesions by laparoscopy or laparotomy. The purpose of a classification system is to specify the relationship between extent of disease and outcome of therapy and to create homogeneous patient groups for comparison of treatment outcomes.

Acosta et al. (1973) introduced a staging system based on the site of the endometriotic lesions and the extent of the adhesions. Three classifications, mild, moderate and severe, were thus formed. This classification system proved to be of value in the prognosis of pregnancy after conservative surgery (Acosta et al., 1973). Subsequently Kistner et al. (1977) and Buttram (1978) proposed classification systems. As none of these classification systems attained general acceptance, a committee appointed by the American Fertility Society devised a classification system (1979). In the revised American Fertility Society classification of endometriosis (1985) a more comprehensive point system to differentiate between ovarian and peritoneal disease was employed. In addition, differentiation between superficial and deep endometriosis of peritoneum and ovaries was provided. The characterization of adhesions was more detailed, allowing for differentiation between filmy and dense adhesions.

Brosens et al. (1985) pointed at problems in using classification systems in evaluating medical therapy. They stated that the effect of treatment on the staging of endometriosis cannot be compared under two different conditions of ovarian activity. If the second laparoscopy upon completion of the treatment is performed in the presence of weak or completely suppressed ovarian activity, the peritoneal lesions seem smaller than they would be in the presence of normal cyclic ovarian activity. In that case hemorrhage, secretion, inflammatory reaction or fibrosis increase the size of the implants considerably. They also questioned the value of assessing the depth of the peritoneal and ovarian lesions, since in their view there is no reason to believe that deep implants have a worse prognosis in infertility than superficial implants. Olive and Haney (1986) pointed at some problems inherent to all classification systems. They stressed that the parameters used are heterogeneous. Staging includes such different and incomparable items as activity of disease, residual or inactive disease, adhesions, and encapsulated ovarian endometriomata. Moreover, there is no distinction between primary and recurrent disease. According to these authors the assumption that more disease results in lower pregnancy rates has never been verified. They suggested that the use of multivariate logistic regression analysis would indicate the probability that a given location of the endometriotic lesion or the quantity of disease will be associated with pregnancy.

It can be concluded that no classification system serves the purpose of specifying a relationship between extent of disease and outcome of therapy. The major gain of any classification system is that it demands careful and systematic inspection of the abdominal cavity.
2.1.3 Epidemiology

Prevalence
The true prevalence of endometriosis in the general population is unknown. Many women with endometriosis are asymptomatic and therefore unaware of its presence. Although endometriosis is associated with infertility, women with endometriosis conceive without treatment, and remain undiagnosed. Furthermore, the prevalence depends heavily on the diagnostic tools used, the population studied, the investigator's level of interest in and knowledge of the disease. Consequently the figures obtained do not represent the prevalence of the disease in the general population. In 1953 Scott stated: "If serial section of all pelvic tissue were feasible might not all 40 year old women with patent tubes and normal menstrual cycles regardless of parity reveal some endometriosis?"

In the era before laparoscopy became available, the figures for the prevalence were based on large series of laparotomies. Figures between 5.6 and 52% were found depending on the indication for laparotomy (Ranney, 1970; Kistner, 1975; Williams and Pratt, 1977; Nikkanen and Puurnonen, 1984). Endometriosis was found to be the only cause of infertility in 58% of 968 consecutive patients undergoing major surgery for the preservation or enhancement of fertility (Buttram and Reiter, 1985b).

The prevalence of endometriosis as diagnosed by laparoscopy varies depending on the indication for the laparoscopy, i.e. tubal sterilization, chronic pelvic pain, unexplained infertility, request for reversal of sterilization.

Hasson (1976) reviewed the findings of 10 studies in 3346 patients who underwent laparoscopy for various reasons; the prevalence of endometriosis ranged from 4 to 33%.

The prevalence of endometriosis as diagnosed by laparoscopy was 1.4 to 5% in patients undergoing tubal sterilization (Hasson, 1976; Drake and Grunert, 1980a; Strathy et al., 1982; Bouckaert, 1984; Trimbos et al., 1984). In a comparable group of patients this figure rose to 10 to 18% if special attention was paid to diagnose endometriosis (Kresch et al., 1984; Dodge et al., 1986; Moen, 1987).

Endometriosis was diagnosed at laparoscopy for chronic pelvic pain in 8.5 to 47% (Chattman, 1976; Goldstein et al., 1980; Kresch et al., 1984; Peters et al., 1986). Endometriosis was diagnosed at laparoscopy in patients with unexplained infertility in 21 to 51% (Peterson and Behrman, 1970; Hasson, 1976; Goldenberg and Magendantz, 1976; Katayama et al., 1979; Drake and Grunert, 1980a; Strathy et al., 1982). Endometriosis is not a chance finding in women who have undergone tubal sterilization (Fakih et al., 1985); in women requesting reversal of sterilization pelvic endometriosis was diagnosed in 18% (Dodge et al., 1986). This high prevalence of endometriosis in women with occluded tubes seems difficult to understand if endometriosis is related to retrograde menstruation. These cases of endometriosis were either missed during the laparoscopy for sterilization, or they developed from early non-visible endometriosis.
Age

Kistner (1975) reported a median age of 37 with 15% of patients being under 30. The age at diagnosis by surgery does not reflect age at first recognition of the disease. More recent studies indicated an average age of 27 to 29 at diagnosis (Buttram, 1979; Sulewski et al., 1980; Rock et al., 1981; Wheeler and Malinak, 1981). The average age of patients with mild, moderate and severe endometriosis was not different in 206 patients operated upon by Buttram (1979). Therefore it seems that the age at diagnosis rather reflects the age at which patients seek help than the age at which the disease occurs. Of equal importance is the age at which physicians are willing to perform a laparoscopy in patients presenting with pelvic pain. The youngest histologically confirmed case of pelvic endometriosis in the literature may be the 10.5 year old girl reported by Goldstein et al. (1980).

In adolescents endometriosis was reported, associated (Hanton et al., 1967; Schiffrin et al., 1973; Goldstein et al., 1980; Baker et al., 1982; Sanfilippo et al., 1986) or not associated with menstrual outflow obstruction (Moore et al., 1967; Bullock et al., 1974; Chaetman and Ward, 1982).

A few cases of recurrence or reactivation of endometriosis in postmenopausal women were reported (Kempers et al., 1960; Punnonen et al., 1980; Djursing et al., 1981; Huybregts et al., 1984).

Ethnic factors

Initially, endometriosis was thought to be solely a disease of white women (Ridley, 1968). Lloyd (1964) reviewed 803 cases of major gynecologic surgery; the prevalence of endometriosis was 6.9% in black and 7.7% in white women. Chatman (1976) reported an prevalence of 21% in black women laparoscoped for various indications. A slightly higher rate of endometriosis was reported in Japanese than in Hawaiian and Caucasian patients (Miyazawa, 1976). Moeloek et al. (1984) reported a prevalence of 32% in patients in Jakarta, as diagnosed by laparoscopy for infertility reasons.

Reviewing the studies on ethnic influences it can be concluded that the racial comparisons are confounded by socioeconomic status, age distribution, availability of medical care, access to contraception, cultural differences regarding childbearing patterns, attitudes toward menses and pain and health care-seeking behavior of patients. The differences in the characteristics of available medical care may alter the probability that existing disease will be diagnosed (Houston, 1984). Similarly, the much quoted psychological characteristics linked to the typical patient with endometriosis, i.e. overanxious, intelligent, egocentric and a perfectionist (Kistner, 1975), are probably related to the above-mentioned confounding variables.

2.1.4 Symptomatology

The characteristic signs and symptoms associated with endometriosis are listed in Table 2.2. The relative frequency of each of the symptoms depends heavily on the

population studied. Between 25 and 30% of women found to have endometriosis at laparoscopy are completely asymptomatic (Kistner, 1984).

The etiology of dysmenorrhea associated with endometriosis is not clear. Direct peritoneal inflammation and irritation by ectopic menstrual debris, mechanical stretching of peritoneal surfaces or hypercontractility secondary to prostaglandins produced by ectopic endometrium may be responsible. Dysmenorrhea is reported in 45 to 94% of endometriosis patients (Audebert et al., 1979; Greenblatt and Zingounis, 1979; Buttram, 1979; Biberoglu and Behrman, 1981). The presence of retrograde spilling of blood in patients with endometriosis was not related to the presence of dysmenorrhea (Liu and Hitchcock, 1986). The severity of pain did not correlate with the severity of the disease in 206 patients studied by Buttram (1979). This discrepancy between pain and severity of the disease as judged by laparoscopy may well be related to different types of endometriosis, intra- and retroperitoneal. In this concept retroperitoneally located endometriosis will be responsible for abdominal pain (Vasquez et al., 1984).

Dyspareunia is a common symptom and may play some role in the reduced fertility (Kistner, 1975). The occurrence but not the degree of dyspareunia correlated with the extent of the disease in the patients studied by Buttram (1979).

Unusual symptoms are catamenial pneumothorax or hemoptyysis (Lattes et al., 1956; Foster et al., 1981; Hibbard et al., 1981; Slasky et al., 1982), subarachnoid hemorrhage (Lombardo et al., 1968), compression of the sciatic nerve (Bergqvist et al., 1987b) and acute abdomen secondary to rupture of an endometriotic cyst (Raney, 1970).

Perimenstrual hematuria may point to kidney or bladder involvement (Hajdu and Koss, 1970; Moore et al., 1979; Gantt et al., 1981). Ureteric obstruction may lead to kidney loss (Laube et al., 1985).

The literature on the association between endometriosis and infertility will be reviewed in paragraph 2.2.

2.1.5 Diagnosis

The diagnosis of endometriosis should be suspected by history, corroborated by pelvic examination and verified by endoscopy and biopsy (Kistner et al., 1984). The clinical diagnosis may be established in 80 to 85% of the cases before surgery (Gray, 1960; Acosta et al., 1973). The most common physical findings are small, often
tender, fixed nodules, which may be felt behind the uterine cervix. Conceivably,
tenderness of these nodules is more likely to be demonstrated if the pelvic exami-
nation is performed during the late luteal phase of the menstrual cycle (Goldstein et
al., 1980). The nodules consist of inflammation and scarring around small en-
dometriomata of the cul-de-sac, the uterosacral ligaments, the posterior peritoneal
surface of the cervix, or the anterior peritoneal surface of the rectosigmoid bowel
(Ranney, 1980). Nodularity of the cul-de-sac and the uterosacral ligaments was
found in approximately 25% of patients with mild endometriosis, 30% of patients
with moderate and 50% of patients with severe disease (Buttram, 1979). A tender,
semifixed, firmly cystic enlargement of one or both ovaries, usually in the 3-4 cm
range and seldom exceeding 5 cm in diameter may be palpated (Ranney, 1980).
Fixed retroversion or retroflexion of the uterus is a variable finding with a frequency
of approximately 40 to 50% in women with endometriosis, related to the severity
of the disease (Buttram, 1979).
Ultrasound proved to be of little help in diagnosing endometriosis. Endometriomata
cannot be distinguished from other pelvic masses by ultrasound. (Goldman and
Minkin, 1980; Friedman et al., 1985).
If extensive endometriosis of the gastrointestinal tract is suspected, X-ray examina-
tion of the colon by barium enema may be performed, but is never conclusive (Gray,
1966). Intravenous pyelography or renal ultrasound may reveal hydronephrosis or
renal atrophy secondary to ureteral obstruction (Langmade, 1975; Moore, 1979;
Laube et al., 1985).
Chihal et al. (1986) reported on the use of serum endometrial antibodies as an aid
in the diagnosis of endometriosis. A significant elevation of antibodies was found
in 74% of patients with endometriosis, whereas fertile control subjects consistently
had normal baseline antibody titers. There was no correlation between the en-
dometrial antibody titers and the stage of endometriosis. They also suggested that
sequential determination of endometrial antibody titers could be helpful in assessing
the efficacy of pharmacological therapy and the possible recurrence in patients with
the disease.
Ca-125 is a glycoprotein with a molecular weight of approximately 200,000 daltons
that is expressed on the cell surface of some derivatives of embryonic coelomic
epithelium. Bast and coworkers (1983) applied an immunoradiometric assay to de-
tect CA-125 in serum. They found that 82% of patients with ovarian carcinoma,
but less than 1% of apparently healthy controls had elevated serum levels of
CA-125. Elevated CA-125 values in serum have been observed in benign conditions
as well, e.g. in endometriosis, acute pelvic inflammatory disease, unexplained infer-
tility, in pregnant women and during menstruation (Pittaway and Fayez, 1986). Pa-
tients with advanced endometriosis have significantly elevated CA-125 serum levels,
compared with normal controls (Barbieri et al., 1986). The level of CA-125 appears
to be related to the severity of the disease (Pittaway and Fayez, 1986). The sensitivity
of the test, however, appears to be too low for it to be of value in screening patients
for endometriosis (Patton et al., 1986; Barbieri et al., 1986; Pittaway and Fayez,
Table 2.3 Sensitivity, specificity, positive predictive value and negative predictive value for CA-125 and endometrial antibodies determinations and prevalence of endometriosis

| CA-125 > 35 U/ml | 0.14 | 0.93 | 0.50 | 0.69 | 0.32 | Patton et al., 1986 |
| CA-125 > 35 U/ml | 0.17 | 0.98 | 0.83 | 0.63 | 0.41 | Barbieri et al., 1986 |
| CA-125 > 16 U/ml | 0.54 | 0.91 | 0.79 | 0.76 | 0.39 | Pittaway and Faye, 1986 |
| Endom Antibodies + | 0.74 | 1.00 | 1.00 | 0.74 | 0.58 | Chiha, 1986 |

1986). CA-125 may be a useful marker for following the course of disease in endometriosis (Patton et al., 1986).

Table 2.3 shows the sensitivity, the specificity, the positive predictive value and the negative predictive value of the determination of CA-125 at two cut-off levels and for the determination of serum endometrial antibodies, as calculated from the data of Patton et al. (1986), Barbieri et al. (1986), Pittaway and Faye, (1986) and Chiha, 1986. Table 2.3 shows a low sensitivity for the CA-125 determination in serum, which is, as expected, higher at a lower cut-off level. The sensitivity for the determination of serum endometrial antibodies is higher than that for CA-125 at either cut-off level. Endometrial antibodies are more specific for endometriosis than the antibodies against CA-125, as shown above. The sensitivity remains too low for it to be of value in the screening for endometriosis in the general population, or even in an infertility population.

Laparoscopy remains the mainstay in diagnosing endometriosis. It has to be kept in mind that laparoscopy is a surgical intervention with certain inherent risks (Persson et al., 1983; Levy et al., 1985; Bergqvist and Bergqvist, 1987a). Laparoscopy allows grading and classification of the disease and biopsies can be taken to confirm the diagnosis by histology. A high level of suspicion has been shown to be of influence in diagnosing endometriosis during laparoscopy (Dodge et al., 1986). Familiarity with the different macroscopic appearances of early minimal endometriosis (vide infra) is of equal importance (Goldstein et al., 1980; Redwine, 1985).

The phase of the cycle during which laparoscopy is performed is important. Liu and Hitchcock (1986) diagnosed endometriosis in 43% of patients undergoing laparoscopy for sterilization during menstruation. This figure is manifold higher than the normally quoted 1.5 to 5% for patients undergoing sterilization (Hasson, 1976; Drake and Grunert, 1980a; Strathy et al., 1982; Bouckaert, 1984; Trimbo et al., 1984). During menstruation the productive activity of the lesions is apparently at its highest level. This changes the macroscopic appearance of these lesions considerably.

Brosens et al. (1985) stressed the fact that laparoscopy for staging of endometriosis should be performed in the presence of normal ovarian activity, since the implants are evaluated in terms of activity rather than number of cells. Evers (1987) compared the number and the cumulative size of the implants before and after treatment in two groups of patients. In the first group the second look laparoscopy was per-
formed at the end of the last treatment cycle, in the second group it was performed
in the follicular phase of the second menstrual cycle after the end of treatment. The
differences in the parameters measured between the two groups were statistically sig-
nificant. He pointed out that the second-look laparoscopy for evaluation of the
result of medical treatment of endometriosis should not be performed during ovar-
ian suppression.

To ensure complete evaluation, inspection of the pelvis in a standardized clockwise
or counterclockwise fashion is necessary. Number, size and location of endometrio-
tic implants, plaques, endometriomata and/or adhesions should be recorded (R-
AFS, 1985). In a study by Jenkins et al. (1986) the ovaries were shown to be most
commonly involved, followed by the anterior vesicouterine fold, the posterior cul-
de-sac and the uterosacral ligaments.

At laparoscopy, early ovarian endometriotic lesions appear on the surface of the
ovary as small reddish-blue implants, later cysts appear that seldom reach a di-
ameter of more than 5 cm. The cysts are filled with a brown or black fluid. En-
dometriosis should be suspected when adhesions or fixed ovaries are found, together
with normal Fallopian tubes. Not infrequently, manipulation of the ovaries reveals
endometriosis either on the undersurface of the ovary or on the adjacent peritoneum
of the ovarian fossa, a predilection place for endometriosis. Sometimes associated
adhesive disease or large ovarian endometriomata may obscure visualization to the
extent that evaluation is not possible.

A biopsy of suspected peritoneal lesions with subsequent histological examination
confirms the diagnosis in 72% of the cases (Portuondo et al., 1982). If light
microscopy is combined with scanning or transmission electron microscopy this
figure rises to 83-85% (Vasquez et al., 1984; Murphy et al., 1986).

In endometriomata a histological diagnosis of endometriosis based on the presence
of endometrial glands and stroma is not always possible, since the epithelial lining
of a cyst may have lost its typical appearance. Due to the cyclic hormonal influences
bleeding into the lesions can occur with considerable tissue distortion and subse-
quent adhesions. Histologically these areas cannot be readily diagnosed as en-
dometriosis, since endometrial glands and stroma are not recognizable. In such
cases the presence of granulation tissue, fibrous tissue and hemosiderin-laden macro-
phages are indicative of the diagnosis of endometriosis.

The laparoscopic, macroscopic, appearance of peritoneal endometriosis varies con-
siderably. The laparoscopic diagnosis of peritoneal endometriosis is traditionally
made on dark pigmented spots on the peritoneum covering the uterosacral ligaments
and cul-de-sac. It can be argued that the black pigmented areas, the classic picture
of endometriosis, are the late consequences of the cyclic growth and regression of
the endometriotic lesions. One should always keep in mind that at laparoscopy only
the sequelae of endometriosis are seen and recognized as endometriosis, such as
hemorrhage, adhesions, accumulation of fluid and inflammatory reaction.

Goldstein et al. (1980) noted in adolescents that early endometriosis did not always
appear as the characteristic black lesions, but sometimes as hemorrhagic areas.
Redwine (1985, 1987) classified endometriotic implants by color(s) of first impression. He described clear papules, red, white, yellow or black. When specific types of lesions were clustered, an evolutionary change in appearance of endometriosis with advancing age was suggested. The typical black lesions occurred at a later stage in the evolution of the disease.

Jansen and Russell (1986b) reported on the existence of unpigmented endometriosis. They defined several distinctive appearances of these endometriotic lesions: white opacification of the peritoneum, glandular excrescenses on the peritoneal surface, red flamelike lesions of the peritoneum and isolated or otherwise unexplained adhesions between the undersurface of the ovary and the ovarian fossa. They also documented progression from nonpigmented to pigmented lesions, confirming the biologic continuum from nonpigmented to pigmented endometriosis.

Vernon et al. (1986) correlated the macroscopic appearance of endometriotic lesions (petechial or reddish, intermediate or brown and powderburn or black) with prostaglandin F synthesis of these lesions. They found that the petechial lesions were biochemically more active than the black lesions.

Peritoneal defects of the type described by Allen and Masters (1955) are frequently associated with endometriosis (De Brux et al., 1968; Chatman, 1981; Chatman and Zbella, 1986). Brosens et al. (1984b) documented microscopic implants of endometriosis on the surface of the peritoneum by scanning electron microscopy (SEM) in patients with unexplained infertility in whom no endometriosis was seen at the time of laparoscopy. Likewise, Murphy et al. (1986) diagnosed endometriosis by SEM in 25% of specimens thought to represent normal mesothelium at laparoscopy. Vasquez et al. (1984), combining the techniques of scanning electron microscopy and light microscopy, revealed three topographically and morphologically different types of endometriosis: intraperitoneal endometriotic polypos with no glandular openings but associated with deeper endometriotic glands and stroma; intraperitoneal endometriotic foci with surface epithelium, glands and stroma; and retroperitoneal small lesions with few glands and scant stroma.

From these observations on the laparoscopic appearance of endometriosis it can be concluded that within the AFS classification of mild endometriosis there is a wide variation in severity of lesions, ranging from submicroscopic retroperitoneal and intraperitoneal lesions to a variety of macroscopically visible lesions. The least impressive lesions are, biochemically, probably the most active (Vernon et al., 1986). Future research might very well learn that the proportion of these "minor macroscopic" lesions in a given patient correlates much better with the severity of the disease than do the stages of the AFS classification which are presently employed to characterize endometriosis. Within individual lesions different histological patterns are found (Vasquez et al., 1984; Scheppe, 1984b). This heterogeneity corresponds well with conflicting reports on peritoneal fluid prostaglandins in mild endometriosis and with the apparent lack of correlation between severity of disease and symptoms. The relative proportion of endometrial glands, stroma and vascularization in the individual endometrial implant will depend on previous episodes of bleeding.
resorption of blood pigments, inflammatory reaction and scarring. Cornillie et al. (1986) showed that endometriotic secretory changes were different from those seen within the uterine endometrium. Full secretory transformation of endometriotic glands was lacking and a wide variation of cellular differentiation was seen within different foci as well as within the same implant. They also showed that secretory differentiation of endometriotic epithelial cells was present only when the ectopic stroma had a well-developed microvasculature, with blood capillaries present near the glandular epithelium. They suggested that the different microvascular supply of eutopic and ectopic endometrium might account for the differences in hormonally modulated synthesis of steroid receptors and tissue differentiation (Cornillie et al., 1986).

The differences in histological patterns and cyclicity of the ectopic foci, in contrast to eutopic endometrium, correlate with reports of variability in concentration of steroid receptors (Tamaya et al., 1979; Jänne et al., 1981; Gould et al., 1983; Värikko et al., 1985). Consequently a heterogeneous response to hormonal changes and hormonal therapy can be expected from the different lesions.

Considering these features of mild endometriosis Brosens et al. (1981, 1984a) proposed the Leaven classification of endometriosis. In this classification a clear distinction has been made between the uncomplicated stage and the complicated stage of endometriosis. The uncomplicated stage includes intraperitoneal and retroperitoneal lesions; in the complicated stage the extent and degree of distortion of the pelvic organs can be graded according to a point system as proposed by the AFS. These two stages represent two different diseases, with a different therapeutic approach and a different prognosis with regard to fertility.

2.1.6 Management

The management of endometriosis depends on the stage of the disease, the severity of symptoms, the age of the patient and the presence of infertility. Goals of treatment are relief from pain and restoration of childbearing potential. Therapeutic modalities include medical and surgical treatment or a combination of the two. It is beyond the scope of this thesis to discuss in detail the different treatment possibilities. Recent comprehensive reviews on endometriosis treatment are those by Schwepe (1984a), Buttram and Reiter (1985b), Schmidt (1985), Barbieri and Ryan (1985), Daniel (1985), Gordts et al. (1984), Olive and Haney (1986) and Andreyko et al. (1987).

Before the, now widespread, use of laparoscopy only symptomatic endometriosis was treated. Asymptomatic endometriosis diagnosed by laparoscopy is now commonly treated as well, mainly in infertile women. Controversies exist on the necessity to treat asymptomatic mild endometriosis in infertile patients in order to improve their fertility chances (Seibel et al., 1982; Hull et al., 1987; Thomas and Cooke, 1987b). These controversies are related to the discussion whether endometriosis is causally related to infertility.
Another controversy is the duration of medical therapy. A long-term estrogen-progestogen therapy was based on the supposedly beneficial effect of pregnancy on endometriosis (Kistner, 1975). Conversely, a 2-month therapy was shown to produce a stronger effect on the implants than a 4-month therapy in a small group of patients (Brosens et al., 1987). It needs further investigation to find out whether the advantages of a short-term medical therapy are supported by increased pregnancy rates.

Less debate exists on the value of treating mild endometriosis in order to prevent deterioration of the disease (Devereux, 1963; Ranney, 1970; Andrews, 1980; Schmidt, 1985; Thomas and Cooke, 1987a), although it has to be emphasized that the natural course of the disease is far from clear.

Reviewing the literature on therapeutic approaches of endometriosis-associated infertility Olive and Haney (1986) found that many medical treatments have proven effective in combating the histological manifestations of endometriosis, but that there is no evidence validating the efficacy of a single medical approach in treating infertility. Regarding surgical therapy they stated that in the presence of anatomical distortion secondary to adhesion formation surgical intervention is crucial to enhance the chances of conception. The value, however, of removal of implants by excision, cauterization or laser vaporization to overcome infertility has yet to be demonstrated. Randomized clinical trials with appropriate controls should be instituted to assess the different therapeutic options for endometriosis-associated subfertility.

In summary, it can be concluded with regard to the management of endometriosis-associated infertility that patients with recently diagnosed mild endometriosis can be managed expectantly for a period of time, provided that every effort is made to correct additional infertility factors (Schenken and Malinak, 1982; Seibel et al., 1982; Portuondo et al., 1983; Kable and Yussman, 1985; Olive et al., 1985a; Hull et al., 1987).

2.1.7 Recurrence

Recurrence of endometriosis after conservative surgical treatment varies from 7% to 47% (Green, 1966; Andrews and Larsen, 1974; Hammond et al., 1976; Andrews, 1980; Wheeler and Malinak, 1983). At the time of surgery it is not possible to remove all endometriotic lesions. Microscopic endometriosis, not discernible to the naked eye, will remain (Acosta et al., 1973; Murphy et al., 1986; Dmowski, 1987). Recurrence of endometriosis after medical therapy varies from 29% to 51% (Dmowski and Cohen, 1978; Greenblatt and Tzingounis, 1979; Moore et al., 1981; Barbieri et al., 1982; Dmowski et al., 1982; Buttram, 1985a; Schmidt, 1985). The difference may be explained by the length of the follow-up period and by the way recurrence is diagnosed, i.e. by recurrence of signs and symptoms of endometriosis, by laparoscopy with or without histological confirmation or by the need to perform a repeat laparotomy.
It is not clear whether the recurrence noted after cessation of treatment represents real recurrence, i.e. de novo formation, or rather persistence of endometriotic lesions. Biopsy specimens taken during repeat laparoscopies at the end of a treatment course for endometriosis repeatedly show occult inactive endometriosis (Steingold et al., 1987) or active disease, even without laparoscopic (macroscopic) signs of endometriosis (Dmowski and Cohen, 1975; Schweppe, 1984c; Murphy et al., 1986). In a prospective study Wheeler and Malinak (1987) showed in 60 patients that in half of the patients so-called recurrence of endometriosis after conservative surgery actually represented persistence of disease.

Schweppe (1984c) showed that persistent disease after 6 months treatment was correlated with the histological differentiation of the endometriotic lesions at the initial diagnostic laparoscopy. Of the highly differentiated endometriotic lesions two-third disappeared after six month treatment, while of the least differentiated lesions three-quarter of the cases persisted. It has to be kept in mind that, since most repeat laparoscopies are performed during ovarian suppression and not during normal ovarian activity, the results of therapy may be overestimated. After discontinuation of ovarian suppression the disease will return with time (Evers, 1987). During hormonal therapy implants are usually suppressed but not eliminated, regardless of the type of drug administered (Schweppe et al., 1981; Cornillie et al., 1986; Cornillie et al., 1987). This supports the view that most if not all of the recurrence is in fact better defined as persistent disease.

2.2 Endometriosis and infertility

2.2.1 Endometriosis-associated infertility

The association between endometriosis and infertility is well established. Reliable figures are hard to find. Before laparoscopy became available only guesses could be made. A much quoted figure of the incidence of infertility in the presence of endometriosis is 30 to 40% (Kistner, 1975). This figure is derived from a statement of Rubin in 1933 that the expectation of pregnancy when the disease is present is about one-half that in the general population. Assuming that the usual incidence of infertility approximates 15% Kistner (1975) came to the above-mentioned 30 to 40%. If male factors were excluded, endometriosis would probably represent the most common cause of infertility (Kistner, 1984). Endometriosis was found to be the only cause of infertility in 58% of 968 consecutive patients undergoing major surgery for the preservation or enhancement of fertility (Buttram and Reiter, 1985b).

The above-mentioned figures are based mainly on findings in patients with symptomatic endometriosis.
The association of endometriosis, to the extent that it compromises tubo-ovarian contact, with infertility seems beyond doubt. Disagreement exists on the question whether mild endometriosis adversely affects fertility. The prevalence of endometriosis in the general population is not known, as discussed in the section on epidemiology. The finding of a low prevalence in patients during sterilization laparoscopy as opposed to the higher prevalence found during laparoscopy in the course of an infertility workup (Strathy et al., 1982), supports the assumed association between endometriosis and infertility. It has to be emphasized that the data were obtained in a retrospective study and that the difference in parity between the two groups may have influenced the results. The infertility seen in patients with endometriosis is a relative one. Fertility is not an all or none phenomenon; it should be defined as probability of conception (Cramer et al., 1979; Koninckx et al., 1984; Leridon and Spira, 1984). Many women with endometriosis are asymptomatic, remain undiagnosed and conceive without treatment. Collins et al. (1983) showed that in the absence of treatment pregnancies occurred in 58% of 49 couples with endometriosis. The concept of endometriosis-associated subfertility is supported by the following observations.

Endometriosis was diagnosed at laparoscopy in 15 out of 25 patients who failed to conceive after artificial insemination by donor (AID) (Broekhuizen et al., 1980). Jansen (1986a) assessed the impact of mild endometriosis on fertility in 98 patients treated with AID. All patients underwent a diagnostic laparoscopy prior to the start of AID. The mean monthly probability of pregnancy (fecundability) was significantly higher in normal patients than in patients with untreated endometriosis (0.12 versus 0.04). Similar findings were reported by Hammond et al. (1986); they studied factors affecting pregnancy rates in a donor insemination program and found that endometriosis significantly reduced fecundability (0.04), while optimal pregnancy rates were obtained in couples with azoospermia (0.17) or no female infertility factors (0.20).

Studies on the effect of different treatment modalities of mild endometriosis provide comparable figures. These studies look at the monthly fecundity rate (MFR) and the cumulative pregnancy rate after medical and surgical treatment of patients with mild endometriosis in comparison to expectant management. The results in the expectant management group supposedly represent the background pregnancy rate, i.e. the 'normal' fecundity of patients with mild endometriosis. The results of expectant management of mild endometriosis are shown in Table 2.4. These data show that the presence of mild endometriosis reduces the monthly probability to get pregnant, since the probability of conception in the normal couple is estimated to be between 0.20 and 0.30 per cycle (Edmonds et al., 1982). This leads for the mild endometriosis patient to a pregnancy rate after one year in the low range of the normal population (Leridon and Spira, 1984; Jansen, 1986a; Olive and Haney, 1986). These data have to be interpreted with some caution. The MFR is known to be influenced by several factors. These include the duration of infertility prior to diagnosis, the time of
Table 2.4 Expectant management in mild endometriosis (MFR = monthly fecundity rate)

(Modified after Olive and Haney, 1986)

follow-up, the influence of other infertility factors, the influence of previous, surgical or medical treatment. If other factors are present that contribute to subfertility, like a suboptimal semen analysis or ovulatory disturbances, the MFR will drop considerably. Not all studies correct for these confounding variables. Additionally, it has to be noted that in most studies expectant management is not the same as no treatment, since the laparoscopy during which endometriosis is diagnosed and the concomitant tubal lavage, peritoneal fluid sampling and the occasional D & C may well influence future fertility. Moreover, expectant management may and may not include correction of other infertility factors.

In summary, the association between endometriosis and infertility is based on the high prevalence of endometriosis diagnosed during laparoscopy in patients with infertility as compared to the prevalence in patients undergoing laparoscopy for sterilization. As mentioned above these prevalence figures should be interpreted with caution. The association between mild endometriosis and infertility is supported by the fact that mild endometriosis reduces fecundability in patients treated for infertility with artificial insemination by donor and by the finding of a reduced fecundability compared to the general population in patients who are not treated for their endometriosis, but in whom expectant management is pursued for a certain period of time.

2.2.2 Possible causes of infertility in endometriosis

The association between endometriosis and infertility is easy to understand when extensive endometriosis with its accompanying adhesions distorts pelvic anatomy and impairs tubo-ovarian relationship and ovarian physiology. Ovarian adhesions may cause entrapment of oocytes despite normal ovulation. Tubal occlusion secondary to endometriosis is rare. Uterotubal obstruction due to intraluminal endometriosis has been reported (Ayers, 1982; Gordts et al., 1983; Fortier and Haney, 1985).

The assumed association between mild endometriosis, where Fallopian tubes are patent and their motility not impeded by adhesions, and reduced fecundability is difficult to explain. Despite the fact that a causal relationship has not been proven,
infertile patients with mild endometriosis are almost invariably treated. Thomas and Cooke (1987b) were not able to show that either treatment or elimination of asymptomatic endometriosis affected future fertility. Nevertheless, the cumulative pregnancy rate of the treated patients was well below that of the general population. It was in the same range as that of the patients with unexplained infertility, i.e. patients without any demonstrable abnormality. Based on their results they questioned a causal role for mild endometriosis in infertility.

In mild endometriosis several mechanisms interfering with fertility potential have been proposed (Muse and Wilson, 1982a). These include disturbances of folliculogenesis, ovulation, ovum pickup and transport, fertilization, preimplantation development and of implantation and/or corpus luteum function.

**Folliculogenesis**
A low level of LH receptors in the granulosa cells of the Graafian follicle and a lack of physiologic increment of the receptor during the follicular phase of the cycle has been demonstrated in patients with endometriosis (Kauppila et al., 1982; Rönnberg et al., 1984). The receptor content was low with and without involvement of the ovaries. From these findings it was concluded that the low LH receptor concentration could result in suppressed LH action and failure of ovulation and corpus luteum formation.

A functional defect of the oocyte in endometriosis, and presumably of the follicle, was postulated by Wardle et al. (1985). They based their conclusion on the finding of a significant reduction of fertilization in their IVF program of oocytes retrieved from patients with endometriosis, compared to fertilization of oocytes from patients with tubal disease and unexplained infertility. Defective folliculogenesis could lead to immature oocytes and impaired fertilization. A reduced fertilizability of oocytes in endometriosis patients was confirmed by O'Shea et al. (1985), but not by others (Chillick et al., 1985; Matson and Yovich, 1986). The discrepancy may be related to prior treatment (Mahadevan et al., 1983; Wardle et al., 1986) or to the different stimulation regimens used (Matson and Yovich, 1986). In a prospective study (Thomas et al., 1986) defects of the developing or developed follicle were demonstrated in 6 out of 18 cycles in patients with minor degrees of endometriosis: a luteinized unruptured follicle occurred in two cycles, in two patients there was inadequate or abnormal folliculogenesis, in one patient a follicular cyst developed and in one patient the follicle ruptured prematurely. Likewise Doody et al. (1988) demonstrated abnormal follicular growth patterns using ultrasound in patients with endometriosis. They found a significant slowing of follicular growth rate and lengthening of the time to ovulation.

**Ovulation**
The combination of endometriosis and ovulatory dysfunction has been reported to range from 10 to 27% (Grant, 1966; Acosta et al., 1973; Soules, 1976; Dmowski
et al., 1976; Starks and Grimes, 1985). The true incidence of endometriosis coexisting with ovulatory dysfunction could not be determined because of the retrospective nature of the studies. In a small prospective study on follicle growth patterns and minor degrees of endometriosis using ultrasonography and endocrinology Thomas et al. (1986) detected anovulation in 11%. Dmowski et al. (1986) showed that treatment of endometriosis more than doubled the effectiveness of ovulation induction in patients with anovulation and endometriosis.

A high frequency of the luteinized unruptured follicle (LUF) syndrome has been associated with endometriosis (Brosens et al., 1978). This high frequency has not been confirmed by others (Marik and Hulka, 1978; Dmowski et al., 1980). The LUF syndrome is defined as the entrapment of the ovum in the follicle at the time of ovulation, while signs of luteinization, i.e. elevated progesterone levels, temperature shift and luteal endometrial maturation, are present and within the normal range. The importance of LUF cycles with regard to infertility asks for repeated occurrence of these LUF cycles. Repeated LUF cycles as diagnosed by serial ultrasound in the same patient are infrequently found (Kerin et al., 1983; Daly et al., 1984; Hamilton et al., 1985), and are mostly restricted to patients with a history of PID and to patients with ovulation induction (Hamilton et al., 1985).

The conflicting data on the incidence of LUF cycles in endometriosis patients mainly depend on the different ways of diagnosing LUF cycles, i.e. laparoscopy to detect an ovulation stigma, steroid concentrations of peritoneal fluid or serial ultrasound of the ovaries (Brosens et al., 1978; Marik et al., 1978; Koninckx et al., 1980b; Dmowski et al., 1980; Donnez et al., 1983; Dhont et al., 1984; Lesorgen et al., 1984; Liukkonen et al., 1984; Thomas et al., 1986).

The etiology of LUF cycles in patients with endometriosis is not known. The occurrence of LUF cycles may be possibly explained by the finding of a low concentration of LH receptors in Graafian follicles in patients with endometriosis (Rönberg et al., 1984). Another explanation for the occurrence of LUF cycles in endometriosis patients was proposed by Malick (1982), who found a decreased serum plasminogen activator activity in a patient with endometriosis. Plasminogen activator activity supposedly plays an important role in follicular rupture (Beers, 1975a; Beers et al., 1975b; Strickland and Beers, 1976). When the ovaries are involved in endometriosis, as is the case in more severe forms of the disease, ovarian function has been shown to be disturbed (Brosens et al., 1978).

From the above-mentioned observations on repetition and on incidence of LUF cycles in patients with endometriosis, it can be concluded that a causal role of LUF cycles in endometriosis-associated infertility has yet to be ascertained.

As has been mentioned in the section on the etiology of endometriosis, it has been hypothesized that LUF cycles allow endometrial cells to implant by creating an intraabdominal hormonal environment with a low concentration of progesterone. In this hypothesis LUF cycles are the cause rather than the consequence of endometriosis (Brosens et al., 1978; Koninckx et al., 1980d).
Ovum pickup and transport
In advanced cases of endometriosis disturbances of ovum pickup due to adhesions and defective tubo-ovarian contact are obvious. Also a peritoneal factor has been implicated: Suginami et al. (1986) demonstrated that, in contrast to peritoneal fluid of controls, peritoneal fluid of patients with endometriosis inhibited ovum capture by the oviductal fimbriae of the golden hamster in vitro. Transport of fertilized ova through the Fallopian tube is effectuated by both muscular and ciliary activity. Ovarian steroids, adrenergic innervation and prostaglandins interact to influence oviducal contractility. Altered tubal transport of fertilized ova resulting in an untimely arrival in the uterine cavity causing implantation failure has been implicated as a cause of infertility in endometriosis patients (Drake et al., 1981). It has been postulated that altered tubal transport is caused by an increased intraabdominal concentration of prostaglandins; in endometriosis patients prostaglandins may be produced by endometriotic implants (Moon et al., 1981; Yiikorkala and Viinikka, 1983; Vernon et al., 1986) or macrophages (Nathan, 1987). Conflicting data, however, have been reported on peritoneal fluid prostaglandin concentration, as will be reviewed in the section on peritoneal fluid constituents. Moreover, attempts to modify ovum transport in vivo have failed to show that prostaglandins accelerate ovum transport, even in the presence of increased tubal contractility (Croxatto et al., 1979). Finally, accelerated tubal transport resulting in earlier entry of the embryo into the uterine cavity as a cause of infertility is not supported by the clinical results of in vitro fertilization and embryo transfer.

Fertilization and preimplantation embryonic development
Phagocytosis of spermatozoa and oocytes by intraabdominal and intrauterine macrophages has been demonstrated (Austin, 1960; Moyer et al., 1970; Hurst et al., 1977; Weissman et al., 1978; Ball et al., 1984; London et al., 1985). Increased phagocytosis of spermatozoa by tubal and intraabdominal macrophages and hence a decreased fertilization rate in women with endometriosis has been suggested by Muscato et al. (1982) and Haney et al. (1983). Halme et al. (1984b, 1987a) documented the presence of more, and more active, intraabdominal macrophages in patients with endometriosis. No significant differences were found regarding phagocytic capabilities of macrophages harvested from peritoneal fluid of endometriosis patients versus controls (Halme et al., 1984b). In another study peritoneal macrophages from patients with endometriosis were shown to exhibit more active phagocytosis of sperm within the first 24 hours in vitro than an equivalent number of macrophages from fertile controls (Stuyt et al., 1987). The remaining spermatozoa, however, were highly motile in both groups, and capable of penetrating hamster ova. From these findings the role of increased phagocytosis by peritoneal macrophages was questioned as a mechanism of infertility in endometriosis. On the other hand, especially in those infertile couples where subfertile semen and endometriosis occur together, increased phagocytosis by macrophages in an advanced stage of activation may bring the number of spermatozoa below a certain threshold level.
It has been postulated that secretory products of macrophages in a more advanced stage of activation may affect spermatozoa, oocytes and early embryos. Peritoneal fluid of endometriosis patients has been reported to decrease sperm penetration of oocytes in the hamster (Chacho et al., 1985, 1987) or mouse (Sueldo et al., 1987), whereas heat inactivated peritoneal fluid has no effect (Halme and Hall, 1982; Sueldo et al., 1987).

Stone and Himsl (1986) determined the rate of sperm recovery at the time of laparoscopy for infertility in 29 patients with and in 77 patients without endometriosis. The number of patients with motile sperm in both groups was similar. The presence of mild endometriosis did not impair sperm motility up to 4 hours after insemination.

A positive influence of peritoneal fluid of normal women on sperm viability and motility has been documented (Balin, 1958; Maathuis et al., 1973; Schellekens et al., 1983). Conversely, Dorez et al. (1985), Oak et al. (1985) and Burke (1986) documented an adverse effect of peritoneal fluid of endometriosis patients on sperm motility and velocity. These effects of peritoneal fluid on sperm velocity have been related to the presence of interferon (IFN) and tumor necrosing factor (TNF). IFN and TNF, products of activated macrophages, present in the abdominal cavity of patients with endometriosis, have been shown to inhibit sperm velocity, while interleukin-1 did not influence sperm motion parameters. Spermatozoa with a decreased motility would become easier targets for macrophages (Hill et al., 1987).

In vitro studies showed that peritoneal fluid of patients with endometriosis adversely affected mouse embryo cleavage and viability in comparison with peritoneal fluid of controls (Morcos et al., 1985; Gerrity et al., 1985). This could not be confirmed by others (Awadalla et al., 1987). Recombinant interleukin-1 was found to be toxic to the growth of 2-cell mouse embryos in vitro (Fakih et al., 1987). The embryotoxicity of interleukin-1 and -2, tested in an in vitro mouse embryo system, was not confirmed by others (Schneider et al., 1987).

In short, peritoneal fluid of patients with endometriosis possibly has an adverse effect on spermatozoa and preimplantation embryos. An increased number of intraabdominal macrophages in an advanced stage of activation may affect fertilization by phagocytosis or by the effect of their secretory products, especially in couples with coincidental male subfertility. It has to be stressed that all the above-mentioned studies except the one by Stone and Himsl (1986) regard in vitro and/or animal experiments with all the related shortcomings.

**Implantation**

That endometriosis-related infertility is caused by factors interfering with implantation and with events in the early postimplantation period has been supported by studies of endometriosis in animal models (Vernon and Wilson, 1985; Hahn et al., 1986) and by reports on a high spontaneous abortion rate in patients with endometriosis (vide infra). The rate of spontaneous abortion in the general population
has been reported between 10 and 20% (Glass and Golbus, 1978; Simpson, 1980a),
although this figure rises sharply when spontaneous abortion is defined as early
embryonic loss based on measurements of human chorionic gonadotropin (Edmonds
et al., 1982; Sharp et al., 1986).
Several studies have reported a high rate, between 31 and 52%, of spontaneous
abortion in patients with endometriosis. Following conservative surgical or
hormonal treatment of endometriosis the fetal wastage has been reported to be signifi-
cantly lower (Petersohn, 1970; Napies et al., 1981; Rock et al., 1981; Olive et al.,
1982; Wheeler et al., 1983; Groll et al., 1984; Wheeler and Malinak, 1985). Metzger
et al. (1986) reported an equally impressive and significant decrease in the spontane-
ous abortion rate among patients who underwent expectant management. They
stressed the importance of inclusion of an appropriate control group to interpret the
spontaneous abortion rate in endometriosis patients before and after treatment.
Women attempting to achieve a pregnancy are a preselected group, distinct from the
general population, in whom spontaneous abortions may be diagnosed more readily
(Jansen, 1982). Moreover, the spontaneous "cure-rate" of women with a history of
early pregnancy loss is high (Glass and Golbus, 1978). FitzSimmons et al. (1987),
in reviewing data on pre- and postdiagnosis spontaneous abortion rates in endo-
metriosis, concluded that the selection bias for women with a history of spontane-
ous abortion together with a preponderance of women with a single loss or a previ-
ous successful pregnancy could contribute to an apparently high rate of spontaneous
loss before evaluation and the appearance of improvement after treatment.
Several theories have been postulated to explain a possible relationship between en-
dometriosis and early abortion. These theories are mainly centered around a suppos-
edly increased concentration of prostaglandins in the abdominal cavity secondary
to endometriosis. Prostaglandins might lead to implantation problems and early
pregnancy loss by acting as luteolytic factors and by increasing uterine contractility
(Drake et al., 1981; Pittaway and Wentz, 1984). The role of prostaglandins in luteo-
lysis in the human is far from clear (review by Chaudhuri, 1985).
An increased incidence of luteal phase abnormalities has been found in patients with
endometriosis (Grant, 1966, 1981; Brosens et al., 1978; Hargrove, 1980; Levine et
al., 1983; Cheesman et al., 1983; Groll, 1984). Brosens et al. (1978), using midcycle
LH peak as the reference point, noted shortening of the luteal phase of the cycle
and a delay in the luteal rise of progesterone in women with endometriosis. A defec-
tive luteal phase is consistent with the finding of a second LH surge (Cheesman et
al., 1982) and with the finding of a low luteinizing hormone receptor concentration
in the Graafian follicle (Rönnberg et al., 1984) in endometriosis patients. Inade-
quate corpus luteum function has been associated with the presence of ovarian au-
toantibodies in patients with endometriosis (Mathur et al., 1982). Incomplete luteo-
lysis with maintenance of an active corpus luteum secreting significant amounts
of progesterone well into the subsequent follicular phase has been documented in
patients with endometriosis by measuring progesterone in the ovarian veins and the
peripheral circulation. This failure of adequate luteolysis was supposed to be
another aspect of the luteal phase dysfunction seen in endometriosis patients (Ayers et al., 1987). Finally, the presence of luteal phase defects in patients with endometriosis has been attributed to hyperprolactinemia (Hirschowitz et al., 1978; Hargrove and Abraham, 1980; Muse et al., 1982b; Radwanska et al., 1987). The finding of hyperprolactinemia in patients with endometriosis could not be confirmed by others (Balasch and Vanrell, 1985).

Other investigators have not been able to demonstrate an increased frequency of luteal phase defects in patients with endometriosis (Rosenfeld et al., 1980; Radwanska and Dmowski, 1981; Pittaway et al., 1983; Balasch and Vanrell, 1985), based on either mid-luteal progesterone levels or on late luteal endometrial biopsy. Finally, no data exist regarding successful treatment of the infertility associated with endometriosis by therapy directed toward luteal phase insufficiency.

All in all, the association between luteal phase defects and endometriosis is not well defined.

An autoimmune response to ectopic endometrium has been proposed as a possible cause of implantation failure in endometriosis patients. Weed and Arquembourg (1980) documented the presence of complement, C_{3}, in uterine endometrium of patients with endometriosis and not in endometrium of patients without the disease. They postulated that an autoimmune response to ectopic endometrium results in a reaction against uterine endometrium eventually leading to implantation failure. In contrast, Bartosik et al. (1987) documented that the presence of complement was not specific for patients with endometriosis, although the absence of complement in eutopic endometrium appeared to be a good predictor of subsequent pregnancies.

Based on these findings Bartosik et al. (1987) postulated that although the presence of endometrial complement is not specific, it may be that complement-fixed endometrial autoantibodies could induce a cytolytic, anti-implantation effect in the endometrium. These specific autoantibodies against endometrium, primarily of IgG and IgA type, were reported to be present in uterine endometrium of endometriosis patients and not of controls (Mathur et al., 1982). At the same time they found endometrial autoantibodies to be significantly elevated in serum, cervical mucus and vaginal secretions in patients with endometriosis compared to controls. The finding of serum autoantibodies to normal endometrium in patients with endometriosis was confirmed by Wild and Shivers (1985). No correlation between the level of autoantibodies and the severity of endometriosis could be detected. Halme and Mathur (1987b) did not find significant levels of endometrial autoantibodies in peritoneal fluid of patients with mild endometriosis.

Saifuddin et al. (1983) reported that both IgG and IgA were more commonly found in endometrium of patients with endometriosis than in controls. There was, however, no difference in immunoglobulin content between fertile and infertile patients, making a causal relation between endometrial antibodies and infertility questionable. Bartosik (1985) could not detect differences in immunoglobulin G in endometria between patients with endometriosis, patients with pelvic inflammatory disease and patients with laparoscopically normal pelvis. Kreiner et al. (1986)
demonstrated anti-immunoglobulin G in a high percentage of patients with endometriosis and of patients with pelvic inflammatory disease. In the absence of disease one false positive test was found. They concluded that endometriosis-associated infertility might be an immune mediated event.

Results of studies on nonspecific immunological functions display a wide discrepancy. Serum complement has been reported to be decreased (Weed and Arquembourg, 1980), increased (Badawy et al., 1984) and not changed (Steele et al., 1984) in patients with endometriosis compared to controls. Quantitative immunoglobulin determinations revealed no differences between patients with and without endometriosis (Badawy et al., 1984; Steele et al., 1984).

Although the hypothesis of implantation failure secondary to autoimmunity in endometriosis is an attractive one, no clear picture arises on the place of autoimmunity in relation to endometriosis-associated infertility from the available literature. The results reported are not unequivocal. Moreover, only a few studies (Mathur et al., 1982; Wild and Shivers, 1985; Halm and Mathur, 1987b) concern parameters of the immune response that are specific for endometrium, i.e. anti-endometrial antibodies. Finally, most findings were not studied in relation to infertility, but only to the occurrence of endometriosis.

In summary, when endometriosis reaches the stage of periaudnal adhesions or tubal occlusion mechanical factors are clearly present. The possible causes of infertility related to minimal and mild endometriosis are multiple as reviewed above. The diversity of the findings in the cited reports is probably primarily due to patient selection. Prior treatment, duration of infertility, stage of the disease, heterogeneity within stages, inappropriate control groups, all influence the different parameters studied.

The whole range of ovulatory disturbances, i.e. anovulation, luteinized unruptured follicle cycles, luteal phase abnormalities, seems to play a role in endometriosis-associated infertility. It is not clear, however, to what extent the incidence of ovulatory disturbances is influenced by patient selection.

The importance of an altered intraabdominal environment secondary to endometrial implants, with consequent changes in macrophages, prostaglandins, immunoglobulins, complement factors, in relation to endometriosis-associated infertility remains to be established.

2.3 Peritoneal fluid and endometriosis

The peritoneal environment, in which (peri)conceptional events like folliculogenesis, ovulation, fertilization and tubal transport of spermatozoa, oocytes and preimplantation embryos take place, has received considerable attention in endometriosis patients in recent years. Peritoneal fluid volume and changes in peritoneal fluid consti-
tients have been studied to elucidate possible causes of endometriosis-associated infertility, especially in the milder forms of endometriosis, where infertility is not easily explained.

2.3.1 Peritoneal fluid volume

Peritoneal fluid is mainly the result of ovarian exudation. Peritoneal exudation, follicular rupture and tubal secretion contribute only a small volume. Peritoneal fluid volume increases from the proliferative to the secretory phase of the cycle (Maathuis, 1977; Maathuis et al., 1978; Koninckx et al., 1980a; Bouckaert et al., 1986a).

Conflicting results have been reported on the influence of endometriosis on peritoneal fluid volume. In the first place this is due to lack of control for the phase of the cycle studied. Secondly, in some of the studies the control group is composed of patients with unexplained infertility, while in other studies patients with endometriosis are compared with fertile controls without endometriosis. Decreased volumes were noted by Koninckx et al. (1980a) in patients with severe endometriosis in the luteal phase of the cycle. Increased volumes have been reported irrespective of cycle dating (Drake et al., 1980b), in the early follicular phase (Koninckx et al., 1980a), in the periovulatory phase (Haney et al., 1981) and in the luteal phase of the cycle (Halmel et al., 1984; Chachou et al., 1985; Oak et al., 1985). Syrop and Halmel (1987) examined peritoneal fluid volume in 426 patients in a retrospective study. Women with endometriosis had a greater peritoneal fluid volume than fertile controls, patients with adhesive disease or unexplained infertility. The volume in the group with unexplained infertility was higher than that in controls. Several other reports have demonstrated no difference in peritoneal fluid volume between patients with and without endometriosis (Rock et al., 1982; Crain and Luciano, 1983; Davood et al., 1984; Damon et al., 1984; Badawy et al., 1985; Mudge et al., 1985; De Leon et al., 1986; Olive et al., 1985; Rezai et al., 1987; Awadalla et al., 1987) neither in the follicular nor in the luteal phase of the cycle. If increased peritoneal fluid volume is found, it seems to be associated not only with endometriosis, but also with unexplained infertility. Therefore it is tempting to suggest that patients with unexplained infertility may be suffering from microscopic endometriosis, not yet discernible to the naked eye.

Syrop and Halmel (1986) correlated peritoneal fluid volume with the subsequent occurrence of pregnancy in patients with endometriosis in a large retrospective study. Endometriosis patients who achieved pregnancy had a significantly lower mean peritoneal fluid volume than those who did not get pregnant. They concluded that peritoneal fluid of patients with endometriosis, through an as yet unknown mechanism or substance, appears to be associated with reduced fertility.

An increased peritoneal fluid volume in patients with endometriosis may be caused by peritoneal irritation secondary to endometrial implants. Peritoneal irritation may
lead to increased vascular permeability and exudation of fluid. The conflicting results of studies on peritoneal fluid volume in endometriosis patients questions the relative importance of the extent to which endometrial implants cause irritation to the peritoneal lining and change peritoneal vascular permeability, resulting in an increased peritoneal fluid volume.

2.3.2 Peritoneal fluid constituents

Macrophages
Macrophages play an important role in maintaining homeostasis. They are involved in phagocytosis and, through their numerous secretory products, in inflammatory and immunological reactions, in remodeling of tissues and healing of wounds. In addition to their regulatory functions macrophages play a central role in cell-mediated immune response; they are both involved in the initiation of the response as antigen-presenting cells, and in the effector phase as inflammatory, tumoricidal and microbicidal cells. Elements of the mononuclear phagocyte system originate in the bone marrow. Mononuclear phagocytes, after development over several days, leave the marrow, pass into the circulation as monocytes, and subsequently within hours to days into the various tissues and compartments of the body, as for instance the peritoneal cavity, where they survive for months as resident macrophages. Functional heterogeneity exists in most populations of macrophages, as a result of variable degrees of differentiation. Once established in the tissues, macrophages can be subjected to a myriad of stimulatory and suppressive signals, particularly in instances of disturbed homeostasis such as inflammation. This alters their morphology, metabolism, and physiology and activates them to adopt various functions (Van Furth et al., 1979; Nathan et al., 1980; Adams and Hamilton, 1984). Their responses include the secretion of some hundred different substances and their biologic activity ranges from induction of cell growth to cell death (Nathan, 1987).

By appropriate stimulation profound alterations can be induced in the physiology of the resident cells. Secondary to nonspecific, nonimmunological inflammatory stimuli, humoral and cellular, resident macrophages produce substances that cause proliferation of monocytes in the bone marrow. These monocytes, with specific functions, after reaching the peritoneal cavity are called inflammatory macrophages.

The alterations that take place in the physiology of the macrophages occur in a stepwise fashion (Cohn, 1978; Adams and Hamilton, 1984; Nathan, 1987):
1. increase in size
2. increase in capacity to spread
3. stimulation of metabolism as reflected by increased numbers of mitochondria, increased aerobic glycolysis, oxygen consumption, hexose monophosphate shunt activity, and increased production of highly reactive intermediate products of oxygen reduction, i.e. superoxide anion, singlet oxygen and the hydroxyl radical
(called the respiratory burst and estimated by measuring the concomitant light emission or chemiluminescence)

4. increased expression of specific surface receptors on the plasma membrane:
   - receptors involved in phagocytosis
     - complement-, Fc- and mannose-fucose-receptors
   - receptors mediating nonphagocytic functions

5. secretion of enzymes and other secretory products:
   - lysosomal hydrolases
   - lysozyme
   - neutral proteases
   - arachidonic acid metabolites, prostaglandins
   - complement components
   - interferon
   - interleukin-1
   - plasminogen activator and inhibitor

6. modification of plasma membrane ectoenzymes

Macrophages exposed to lymphokines and other signals are competent to present antigen to T-lymphocytes, and to display microbicidal and tumoricidal activity. The mediation of macrophage activation by specifically sensitized lymphocytes is achieved by way of soluble mediators collectively referred to as lymphokines. Important factors in regulating development and function of macrophages are the secretory products released from the macrophages themselves, which initiate many complex positive and negative feedback loops. Most functions can be down- as well as up-modulated (Bonney and Davies, 1984).

An important concept in understanding macrophage function and regulation is the heterogeneity of macrophages within any given population. Individual capacities are not necessarily expressed uniformly by all cells (Nelson, 1981; Bursuker and Goldman, 1983). The various capacities of macrophages do not all develop synchronously but rather asynchronously and even disparately (Adams and Hamilton, 1984). Normally peritoneal fluid contains 0.5 to 2.6 x 10^6/ml leukocytes, of which more than 85% are macrophages (Van Furth et al., 1979; Haney et al., 1981; Muscato et al., 1982; Halme et al., 1983; Olive et al., 1985b). Their physiologic function is maintenance of homeostasis, as reviewed above. They are involved in phagocytosis of decaying spermatozoa, removal of blood cells after retrograde menstruation and ovulation.

Haney et al. (1981) reported an increased total number of macrophages in infertile patients with endometriosis compared to infertile patients without endometriosis. The total number of macrophages in both infertile groups was higher than that of a fertile control group. The peritoneal fluid volume was higher as well in the infertile patients with endometriosis. Macrophage concentration did not differ. Muscato et al. (1982) documented in the same patient groups an increased phagocytosis of spermatozoa in vitro by the macrophages of the endometriosis patients, compared to
those of fertile controls. This could not be confirmed by Awadalla et al. (1987) in another study involving two large groups of infertile patients with and without endometriosis, nor did they find an increased total count or concentration of macrophages in endometriosis patients. Studying the number of macrophages inside the oviducts Haney et al. (1983) found a higher number of oviductal macrophages in endometriosis patients. They suggested that oviductal and peritoneal macrophages in endometriosis patients interfere with fertility by increased sperm-phagocytosis. Halme et al. (1982, 1983, 1984b, 1987a) published a series of observations on peritoneal macrophages in endometriosis patients. In fertile patients with open Fallopian tubes they noted a high concentration of macrophages during menstruation which gradually decreased and remained stable during the rest of the cycle. In contrast, infertile patients with occluded tubes had a low concentration compared to fertile controls and to infertile patients with endometriosis. They concluded that macrophages are attracted by retrograde menstruation (Halme et al., 1982). Furthermore, they noted an increased concentration of two proteins, acid phosphatase and neutral protease, in the peritoneal fluid of patients with endometriosis compared to fertile controls. Additionally the macrophages in the patients with endometriosis had higher acid phosphatase expression, which is associated with macrophages of a larger size. They concluded that the macrophages of patients with endometriosis were in a more advanced stage of activation, possibly leading to either phagocytosis of gametes or release of active compounds into the surrounding peritoneal fluid (Halme et al., 1983). Subsequently they reported on a cyclic activation of macrophages in normal women: the activational status of peritoneal macrophages changes during the cycle, showing an increase toward the luteal phase. This cyclic activation appeared to be more pronounced in patients with endometriosis. They suggested that retrograde menstruation or bleeding from ectopic endometrial implants, acting as irritating agents, could attract macrophages and induce differentiation (Halme et al., 1984b). In a larger group of patients they found a significantly higher total number of macrophages in patients with endometriosis compared to fertile controls and compared to patients with unexplained infertility. Furthermore, they extended their observations that macrophages of endometriosis patients were in a more advanced stage of maturation. They suggested that these more advanced macrophages, apart from interfering with reproductive events, may produce factors that might facilitate growth of endometrial implants (Halme et al., 1987a). Peritoneal macrophages of patients with endometriosis were shown to produce increased levels of fibronectin in vitro (Kauma et al., 1987). It was suggested that such an increase might facilitate the implantation of endometrial cells and their subsequent growth in the pelvis.

The concept of more advanced macrophages in peritoneal fluid of patients with endometriosis has been supported by the finding of interleukin-1 (IL-1) in peritoneal fluid of patients with endometriosis, and not in peritoneal fluid of patients without the disease. Peritoneal macrophages of patients with endometriosis and not of controls produced IL-1 when cultured in vitro. Recombinant IL-1 adversely affected
mouse embryo growth (Fakih et al., 1987). As outlined above IL-1 is one of the proteins that is secreted by macrophages in an advanced stage of differentiation. IL-1 concentration in the peritoneal fluid and in vitro IL-1 production did not differ between 49 patients with and 73 patients without endometriosis (Awadalla et al., 1987). It has to be noted that in this last study both groups consisted of infertile patients.

Conflicting data have been reported on the concentration in peritoneal fluid of other secretory products of macrophages in an advanced stage of differentiation, i.e. prostaglandins and complement components (vide chapter 2.3.2, Peritoneal fluid constituents).

Olive et al. (1985b) reported that elevated numbers of macrophages are not exclusive to patients with endometriosis but rather correlate with infertility in the absence of endocrinologic or mechanical disorders. They suggested that patients with high macrophage counts represent a distinct group of which women with endometriosis are only a subset. Syrop and Halme (1986) related peritoneal fluid parameters to subsequent pregnancy outcome. They found that peritoneal fluid macrophage count was not a significant predictor variable. It has to be noted that only macrophage count and not macrophage activity was used as parameter.

Zeller et al. (1987) documented that not only peritoneal macrophages but also peripheral monocytes of patients with endometriosis were in an advanced stage of activation. They suggested that endometriosis may be a systemic autoimmune disease rather than a local disorder. They based their conclusion on the advanced stage of activation of peripheral monocytes and peritoneal fluid macrophages, on the finding of a decrease in the cell-mediated immune response to autologous endometrial antigens (both in vivo and in vitro in rhesus monkeys and in women with endometriosis) and on the finding of an abnormal autoantibody profile in a high percentage of women with endometriosis (Gleicher et al., 1987; Zeller et al., 1987; Dmowski, 1987).

In summary, macrophages in the abdominal cavity are derived from peripheral monocytes arriving there from the bloodstream. They are continuously reacting to stimuli like retrograde menstruation and spermatozoa, provided that the Fallopian tubes are patent. In patients with endometriosis macrophages may also react to bleeding from the ectopic implants. Many studies have found increased numbers and/or concentrations of peritoneal and oviductal macrophages in patients with endometriosis compared to fertile or infertile controls. Macrophages of patients with endometriosis apparently are in an advanced stage of activation. Consequently they may facilitate implantation of endometrial cells and they may influence periconceptional events, either directly by phagocytosis of gametes or indirectly by their secretory products.
Steroid hormones
In regularly cycling women peritoneal fluid estradiol and progesterone levels are comparable to serum levels in the follicular phase of the cycle (Bouckaert, 1984). After the LH surge and subsequent ovulation the peritoneal fluid levels of estradiol and progesterone rise sharply. The increase in estradiol concentration in the postovulatory phase is more gradual than the increase in the progesterone concentration. Postovulatory levels of estradiol in peritoneal fluid rise to 8 to 10 times those of serum, those of progesterone to 20 to 50 times. (Maathuis et al., 1978; Koninckx et al., 1980; Donnez et al., 1982; Zore et al., 1982; Loumaye et al., 1985; Bouckaert et al., 1986b). The cyclic changes in peritoneal fluid concentrations of estradiol and progesterone are directly related to ovarian activity. Women with anovulatory cycles have low values of these steroids (Donnez et al., 1982). The sources of the steroids in the peritoneal fluid are the developing follicle, the contents of the follicle and the luteinizd theca interna (Bouckaert et al., 1986b). In LUF cycles the postovulatory peritoneal fluid levels of progesterone and estradiol remain relatively low, since the steroid rich contents of the follicle do not reach the peritoneal cavity. Measurement of these steroids may aid in the diagnosis of LUF cycles (Koninckx et al., 1980b; Koninckx and Brosens, 1982; Bernardus et al., 1983; Lesorgen et al., 1984). A considerable overlap exists, however, in peritoneal fluid steroid concentrations between normal and LUF cycles (Koninckx and Brosens, 1982). As noticed above (2.2.2) there are conflicting reports on the occurrence and importance of LUF cycles in endometriosis patients.

No significant differences were found in peritoneal fluid concentrations of estradiol and progesterone comparing patients with and without endometriosis, neither in the follicular, nor in the early and late luteal phase of the cycle (Koninckx et al., 1980b; Crain and Luciano, 1983; Dhont et al., 1984; Lesorgen et al., 1984; Ylikorkala et al., 1984b; De Leon et al., 1986). In contrast, Donnez et al. (1983) reported decreased concentrations of estradiol and progesterone in peritoneal fluid of patients with moderate and severe disease in the peri- and postovulatory phase of the cycle.

Prostaglandins
Prostaglandins are biosynthesized from polyunsaturated fatty acids, predominantly arachidonic acid. Arachidonic acid is liberated from cellular phospholipids by the action of phospholipases. After formation of PGG₂ and PGH₂, the prostaglandins PGE₂, PGD₂, PGF₂α, PGI₂ and TXA₂ are synthesized. The more stable metabolites of PGF₂α and TXA₂ are 6-keto-PGF₁α and TXB₂. Biosynthesis and release of prostaglandins from tissues occur in response to various stimuli. Prostaglandins are rapidly metabolized in the lungs.

The role of prostaglandins in ovulation, corpus luteum function and tubal transport has been reviewed by Chaudhuri (1985). Prostaglandins play a role in the mechanism of ovulation, although the exact mechanism is not yet known. The induction of LUF cycles with prostaglandin synthetase inhibitor drugs has been reported (Kil-
lick and Elstein, 1987). The exact mechanism and the role of prostaglandins, if any, in luteolysis in the human remains to be elucidated (Chaudhuri, 1985). In the rabbit the role of prostaglandins in oviductal motility is fairly well established (Chang and Hunt, 1972; Salomy and Goldstein, 1978; Harper et al., 1980). In the human the role of endogenous and exogenous prostaglandins is less clear (Elder et al., 1977; Croxatto et al., 1978, 1979).

The study of peritoneal fluid prostaglandins in relation to endometriosis has received considerable attention in recent years. Sources of prostaglandins in peritoneal fluid are the ectopic endometrium and peritoneal macrophages (Nathan, 1987). Ylikorkala and Tenhunen (1984a) reported that human follicular fluid contains prostaglandins, but that the concentrations of these prostaglandins were not elevated in endometriosis patients. They concluded that the increased concentration of prostaglandins found by some in the peritoneal fluid of patients with endometriosis does not originate from the follicle.

The uterine endometrium produces several different prostaglandins (Wilks et al., 1972; Levitt et al., 1975; Willman et al., 1976; Abel and Kelly, 1979). Likewise ectopic endometrium produces prostaglandins. Moon et al. (1981) measured the PGF content of ovarian tissue with and without endometriosis and found that the endometriotic lesions produced significantly more PGF. Ylikorkala and Viinikka (1983) reported on the production of 6-keto-PGF1α and TxA2 by endometriotic implants. De Leon et al. (1983) demonstrated that peritoneum involved with endometriosis produced significantly more PGF2α and PGE2 than adjacent normal peritoneum. Vernon et al. (1986) measured PGF concentration and in vitro production by endometriotic implants, endometrium and normal peritoneum. They found that endometriotic implants contained and produced significantly more PGF than normal peritoneum. Endometrium contained twice the amount and exhibited five times the capacity to produce PGF than endometrial implants. They also correlated PGF production with different types of endometrial implants, i.e. petechial, intermediate and powderburn lesions. As judged by PGF production petechial implants were biochemically more active than intermediate implants, which in turn were more active than powderburn implants.

Initial studies on peritoneal fluid prostaglandins and endometriosis showed increased concentrations of 6-keto-PGF1α and TxA2 in peritoneal fluid of patients with endometriosis compared to controls (Drake et al., 1981). It was suggested that these prostaglandins could alter tubal function and thus explain infertility in endometriosis patients. Likewise, peritoneal fluid PGF2α and PGE2 were found to be significantly increased in patients with endometriosis (Badawy et al., 1982, 1984). De Leon et al. (1986) compared peritoneal fluid PGF2α, PGE2, 6-keto-PGF1α and TxA2 in the proliferative and the secretory phase of the cycle between patients with and without endometriosis. In both phases of the cycle significantly higher concentrations of all four prostaglandins were found in endometriosis patients. Other studies could not confirm these findings (Rock et al., 1982; Sgarlata et al., 1983; Dawood et al., 1984; Mudge et al., 1985; Rezai et al., 1987). In patients with en-
dometriosis, tubal disease or unexplained infertility Ylikorkala et al. (1984b) found significantly elevated levels of 6-keto-PGF$_{1\alpha}$ and TxB$_2$ compared to controls. Drake et al. (1983) found a marked elevation of 5-keto-PGF$_{1\alpha}$ and TxB$_2$ in a subgroup of patients with unexplained infertility.

In summary, the available literature on peritoneal fluid prostaglandin concentration in endometriosis patients shows either an increase or no changes compared to patients without the disease. Some of the confusion may be attributed to methodological differences, collection procedures, contamination of peritoneal fluid samples with blood, patient- and controlgroup selection and the time of the cycle studied. The presence of invisible microscopic endometriosis may account for high levels of prostaglandins in some patients with unexplained infertility. Within the AFS classification of mild endometriosis different types of lesions are apparently present (Vasquez et al., 1984), characterized by a specific biochemical potential (Vernon et al., 1986).

**Proteins**

The total protein concentration in peritoneal fluid has been reported to be below that of serum (Maathuis et al., 1978; Konincx et al., 1980a). The concentrations of total protein and of various individual proteins in the peritoneal fluid exhibited a cyclic pattern with a significant increase in the luteal phase of the cycle (Konincx et al., 1980a; Bouckaert et al., 1986a). The peritoneal fluid/serum (p/s) ratio of each individual protein showed a significant inverse correlation with its molecular weight (Bouckaert et al., 1986a).

There are few data on the protein content of peritoneal fluid in patients with endometriosis. Bernard and Baumstark (1983) measured total protein concentrations and specific protein concentrations in peritoneal fluid and serum and could not detect differences between patients with and without endometriosis. In patients with endometriosis $\alpha_1$-antitrypsin was elevated in peritoneal fluid versus serum. They concluded that the elevation of the acute-phase reactant $\alpha_1$-antitrypsin supported the suggestion of a local inflammatory process. Comparable results were reported by Fazleabas et al. (1987). They found a significantly higher total protease inhibitory activity in the peritoneal fluid of patients with endometriosis compared to controls in the early luteal phase of the cycle. They suggested that this increase was indicative of a local inflammatory reaction. Since they used total protease inhibitory activity rather than protease concentration, the increase they found is most probably due to the increased peritoneal fluid volume that was found in the early luteal phase of the cycle.

CA-125 levels were ten fold higher in peritoneal fluid compared with serum in both patients with minimal endometriosis and in controls. There was no significant difference in the ratio of peritoneal fluid/serum (p/s) CA-125 levels between endometriosis patients and controls respectively (Williams et al., 1987). The high p/s ratio for CA-125, a glycoprotein with a molecular weight of approximately 200,000 daltons, can only be explained by active production of CA-125 in the peritoneal
cavity. A much lower p/s ratio has been documented for C₁ and C₂, two proteins with a comparable molecular weight (180,000, p/s ratio 0.25 and 260,000, p/s ratio 0.31 respectively; Bouckaert et al., 1986a) that reach the peritoneal cavity by transudation. Apparently the active production of CA-125 into the peritoneal cavity is not different between patients with minimal endometriosis and controls. The authors did not mention, however, whether the controls were normal fertile women. If also women with "unexplained infertility" were included the presumed occurrence of microscopic active endometriosis in this group may have affected the results. It is of utmost importance to know whether in normal fertile women also high p/s ratios of CA-125 can be found.

The studies on those peritoneal fluid proteins that are part of the fibrinolytic system (Malick, 1982; Barzofin et al., 1985) have been discussed in the section on etiology.

2.4 The use of an experimental animal model of endometriosis

Besides naturally occurring endometriosis in nonhuman primates, surgically induced endometriosis in animals has been used to study pathogenesis, etiology and treatment of endometriosis and to study the role of endometriosis in infertility. Successful autotransplantation of endometrial tissue in the peritoneal cavity has been documented for the rabbit (Jacobson, 1922; Schenken and Asch, 1980; Hahn et al., 1985), rat (Vernon and Wilson, 1985; Golan et al., 1986) and monkey (Scott and Wharton, 1957; DiZerega et al., 1980). Surgically induced endometriosis in the monkey is markedly similar in gross and histological appearance to human endometriosis. Moreover, the monkey has a spontaneous menstrual cycle. Most research has been performed on smaller, less costly, animals like the rabbit and the rat.

In addition, heterologous transplants of human uterine and ectopic endometrial tissue to athymic mice were found to implant, grow and respond to steroids (Zamah et al., 1984; Bergqvist et al., 1985a, 1985b).

Pathogenesis and etiology

To test Sampson’s theory of retrograde menstruation as the cause of endometriosis, Scott, Te Linde and Wharton (1950, 1953) conducted several experiments in the monkey. They surgically diverted the cervix from the vagina to the peritoneal cavity in order to create intraabdominal menstruation. Five out of ten monkeys developed adhesions adjacent to the cervix that histologically contained endometriosis. One animal developed endometriosis on the bowel wall and the peritoneum, confirming the ability of menstrual components to induce endometriosis. Spontaneously occurring and induced endometriosis in the monkey was also used
to study the role of steroids in controlling the growth and the development of endometriotic implants (Scott and Wharton, 1957; DiZerega et al., 1980). It was concluded that autotransplanted endometrial tissue was dependent on steroids for maintenance of growth but not for initiation of implantation. Conversely, steroids appeared to play an obligatory role in the development of ectopic endometrial implants in the rat (Vernon and Wilson, 1985).

Another contribution to the pathogenesis and etiology of endometriosis was the observation of the development of endometriosis in Rhesus monkeys secondary to irradiation (McClure et al., 1971; Splitter et al., 1972; Wood et al., 1983). The irradiation supposedly altered the immunological response in the host, promoting proliferation of endometriosis. The decrease in cell-mediated immune response to autologous endometrial antigens found in monkeys with spontaneous endometriosis supports this view (Dmowski et al., 1981).

The ideal animal model to study pathogenesis and etiology of endometriosis will be a cyclically menstruating animal, in which different levels of immunodeficiency, humoral and cellular, and different levels of impeded menstrual egress and/or increased uterotubal reflux can be effectuated independently. This model does not exist.

**Treatment**

The efficacy of various drug regimens, i.e. progestins, DES, danazol, has been tested in surgically induced endometriosis in the monkey (Scott and Wharton, 1955, 1962), the rat (Jones, 1984; Goian et al., 1986) and the rabbit (Hahn et al., 1985). Treatment by medical (GnRH-analogs) or surgical oophorectomy has been shown highly effective in induced endometriosis in monkeys (Werlin and Hodgen, 1983), rabbits (Hahn et al., 1985) and rats (Jones, 1984).

The efficacy of laser-treatment has been demonstrated in surgically induced endometriosis in the rabbit (Keye et al., 1983).

**Infertility**

Schenken and Asch (1980) induced endometriosis surgically in the rabbit and determined the number of corpora lutea and the number of intrauterine pregnancies 14 days after hCG administration and artificial insemination. They found significantly impaired fertility rates (25%) as compared with controls (75%), primarily due to a defect in ovulation. They suggested that the increased peritoneal fluid prostaglandin F levels that were found in rabbits with surgically induced endometriosis could alter follicular rupture, ovum transport, corpus luteum function or implantation, and thus contribute to the infertility seen in endometriosis. In a subsequent study Schenken and Walters (1986) demonstrated a reduced ovulation and recovery rate in rabbits with induced endometriosis. The reduced recovery rate was primarily due to adhesions. Tubal transport of ova was not disturbed.

Hahn et al. (1986) showed in a rabbit model of endometriosis that, in the absence of adhesions, ovulation, fertilization, embryonic cleavage and embryonic transport
were not influenced by the presence of endometrial implants. However, on day 14 of pregnancy only 38% of the embryos had implanted in the experimental group as compared to 83% in intact controls. Likewise, the fertility of normal animals was impaired secondary to intraabdominal installation of peritoneal fluid from rabbits with induced endometriosis. From these results they concluded that the infertility in endometriosis may be associated with a factor in the peritoneal fluid that either prevents implantation or induces early spontaneous abortions.

Dornez et al. (1987) autografted endometrial tissue in rabbits and studied the effect of the implants on ovulation. They recorded the number of corpora lutea three, five and seven days after the administration of hCG, and found a significant decrease of corpora lutea in rabbits with endometrial implants, compared to controls. Histological examination also revealed a high incidence of entrapped ova. These investigators recorded the number of ovulation stigmata only several days after ovulation. Reepithelialization of the stigma may have taken place already at that moment, rendering the recognition of all recent ovulations more difficult. Furthermore, they studied only a small number of animals, while adhesions, distorting the genital tract, were present in 3 out of 5 of these animals.

Werlin et al. (1981) assessed follicular rupture and ovum recovery in the presence of ectopic endometrial tissue in monkeys. If adhesions secondary to endometriosis involved ovaries and fimbriae, ovum recovery and follicular rupture were impaired. Schenken et al. (1984) studied the cycles and fecundity of monkeys with induced endometriosis. In monkeys with moderate and severe endometriosis they observed LUF in 50% of the cycles. The chemical and term pregnancy rates were lower in monkeys with moderate and severe endometriosis compared with controls. The impaired fertility was primarily mediated by failure of follicular rupture and pelvic adhesions.

Vernon and Wilson (1985) showed that the presence of ectopic endometrial tissue in the peritoneal cavity of the rat interfered with fertility. There was a reduction of 30% in the number of embryos at midgestation and a 50% reduction of pups at term. It was suggested that the decreased fecundity was due to impairment of ovulation, fertilization and implantation.

In summary, the studies reviewed show that endometrial implants in animals are associated with decreased fertility primarily due to concomitant adhesions. These adhesions impair ovulation and recovery of the ova. Only few carefully conducted studies have been published employing microsurgical techniques in an attempt to prevent adhesion formation secondary to faulty surgical technique. In the absence of adhesions implantation failure or early embryonic loss appear to affect fertility in animals with endometrium implants.

Chapter 3

Aims of the study

Endometriosis continues to be an enigmatic disease. Most of its etiology and pathogenesis remain obscure. The relation between endometriosis and subfertility is accepted but not understood. Much effort has been directed to elucidate these problems. One way of approach has been the study of peritoneal fluid and its constituents. Peritoneal implants of endometriosis, undergoing monthly changes under the influence of hormones, supposedly evoke inflammatory changes in the abdominal cavity and hence changes in the peritoneal fluid. The presence of inflammatory changes was suggested by an increased peritoneal fluid volume, increased concentrations of prostaglandins, macrophages and proteases and by the presence of adhesions. Changes in the intraperitoneal milieu secondary to peritoneal implants have been incriminated as causal factors in the infertility seen in patients with mild endometriosis, and as etiological factors in the development of endometriosis. Total number, concentration and function of peritoneal macrophages in patients with endometriosis have been correlated both with the development of the disease and with endometriosis related infertility. Likewise, changes in the intraabdominal fibrinolytic system and changes in prostaglandins and proteases have been held responsible for the development of endometriosis and for infertility.

We decided to further characterize the intraabdominal milieu in patients with endometriosis.

The first goal of the present study was to delineate to what extent endometriosis changes the intraabdominal milieu as reflected in changes in peritoneal fluid. The hypothesis was tested that inflammatory changes of the peritoneum secondary to endometrial implants affect the degree of exudation of certain proteins, with concomitant increased peritoneal fluid volume. Additionally, the presence of secretory active and continuously changing endometrial implants possibly evokes an acute-phase response. In chapter 4 the results will be presented of measurements of peritoneal fluid volume and peritoneal fluid/serum ratios of acute-phase proteins in patients with and in patients without endometriosis.

Changes of intraabdominal fibrinolysis have been correlated with the development of endometriosis and with the infertility seen in this disease. To test the hypothesis that a decreased fibrinolytic activity favors the development of endometriosis, we determined factors of the fibrinolytic system in the peritoneal fluid of patients with and of patients without endometriosis. In chapter 5 the results of these studies will be discussed.

Furthermore, we characterized the functional activity of macrophages, besides total cell number and concentration of these cells, in the peritoneal fluid of patients with
endometriosis as compared to patients without the disease. The results of these func-
tion tests, the capacity of the macrophages to phagocytose sheep red blood cells and
the emission of light after phagocytosis of opsonized zymosan, chemiluminescence,
will be discussed in chapter 6.
The influence of endometriosis on peritoneal fluid constituents may be measured
directly. Infertility in endometriosis patients can be and has been correlated with in-
traabdominal changes secondary to the presence of endometriosis. The interference,
however, of endometriosis and possibly peritoneal fluid with ovum development
and maturation, ovulation, fertilization, tubal transport and implantation cannot be
observed directly in the human.
We therefore used an animal model of mild endometriosis to study the influence of
endometriosis on these processes. The model used will be described in chapter 7.
In chapter 8 the influence of endometrium implants in the rabbit on ovulation,
ovum pickup, fertilization and tubal transport will be reported.
The influence of endometrium implants in the rabbit on embryonic development in
the first 24 hours after mating and the results of additional culturing of these em-
bryos in a culture medium will be presented in chapter 9.
Chapter 4

The acute-phase response in endometriosis of women

G.A.J. Dunselman, P.X.J.M. Bouckaert, J.L.H. Evers
(Journal of Reproduction & Fertility, accepted for publication)

Summary

Peritoneal fluid volume was determined and concentrations of C-reactive protein, α1-antitrypsin, acid-α1-glycoprotein, α1-macroglobulin, haptoglobin, complement factors C1 and C4, IgG, IgA and IgM were measured in the supernatant of the peritoneal fluid and in serum by means of a radial-immunodiffusion technique in 25 patients with and in 45 patients without endometriosis. Peritoneal fluid volume was not different between the two groups. The peritoneal fluid:serum ratios for the proteins determined showed a significant inverse correlation with their molecular weight in both groups, indicating that their presence in peritoneal fluid is governed by exudation according to their molecular weight, rather than by active production in, or selective release into the peritoneal cavity. In control patients only, the ratios of most of the individual proteins studied were significantly higher in the luteal than in the follicular phase. We suggest that the high ratio of peritoneal fluid:serum values in endometriosis patients in the follicular phase reflects an additional contribution by peritoneal implants of endometriosis and peritoneal macrophages. The cycle-dependent increase of proteinexudation in the luteal phase of the cycle obscures this additional contribution.

We conclude that endometriosis does not cause marked intraabdominal inflammatory changes. If the presence of peritoneal implants of endometriosis lowers fecundity, the mechanism likely does not involve acute-phase protein synthesis.
Introduction

There is circumstantial evidence that a relationship exists between endometriosis, even in its milder forms, and subfertility, but the cause of this subfertility remains unclear. It has been suggested that peritoneal implants of endometriosis cause an inflammatory reaction of the pelvic peritoneum (Drake et al., 1980; Haney et al., 1981; Halme et al., 1987; Fazleabas et al., 1987). This inflammatory reaction may lead to subfertility by causing changes in the peritoneal environment, in which follicular development, ovulation, fertilization and tubal transport take place, analogous to the intrauterine inflammatory reaction present in intrauterine device users, which lowers the probability of conception by similarly postulated mechanisms (Casslén and Ohlsson, 1981).

Inflammation, as a local response to tissue injury, results in changes in vascular calibre and flow, increased vascular permeability and attraction of leucocytes. Accordingly, an inflammatory reaction secondary to endometriosis may result in increased production of peritoneal fluid (Drake et al., 1980; Haney et al., 1981; Syrop and Halme, 1987a), secretion of prostaglandins (PG) (Ylikorkala et al., 1984; De Leon et al., 1986; Vernon et al., 1986) and protease inhibitors (Fazleabas et al., 1987) and attraction and differentiation of macrophages (Haney et al., 1981; Halme et al., 1987). Conflicting results have been reported on the influence of endometriosis on peritoneal fluid volume and the concentration of PG. More agreement exists on the increased number and on the increased activation of intraabdominal macrophages in patients with endometriosis (see Syrop and Halme, 1987b for review).

Additionally a number of systemic and metabolic changes occur during the acute-phase of inflammation. The ultimate goal of the acute-phase response is the removal of damaged tissue and the repair of the affected organ (Kushner, 1982). In patients with pelvic inflammatory disease acute-phase proteins were shown to be present in serum (Künzig et al., 1985). If peritoneal implants of endometriosis cause intraperitoneal inflammatory changes, this possibly will be reflected in measures of the acute-phase response.

To delineate the extent of inflammatory changes secondary to the presence of peritoneal implants of endometriosis we determined, in addition to peritoneal fluid volume, various indicators of the acute-phase response.

Materials and Methods

Peritoneal fluid was collected during laparoscopy in 70 patients from the pouch of Douglas and the vesicouterine space under direct vision as described by Bouckaert et al. (1986a). The laparoscopies were planned in the early luteal phase of the men-
strual cycle, based on information regarding the length of the previous cycles and the first day of the last menstrual period. The indication for laparoscopy was infertility in 40 patients, abdominal pain in 9 and sterilization in 21. They all had regular cycles, ranging from 23 to 35 days. None of the patients had used oral contraceptives or ovulation inducing drugs or an intrauterine contraceptive device for at least 3 months before the laparoscopy. Patients with occluded Fallopian tubes were excluded. At laparoscopy all patients were carefully screened for the presence of endometriosis. The diagnosis was made on morphological grounds. Endometriosis was identified according to the classification of the American Fertility Society (AFS)(1979).

After collection of the peritoneal fluid, the volume was measured, the fluid was centrifuged and the supernatant stored at -70°C until assayed. Before induction of anaesthesia a 5-ml blood sample was withdrawn, centrifuged and the supernatant stored at -70°C until assayed. In serum and in the supernatant of the peritoneal fluid oestradiol-17β and progesterone concentrations were determined. The values of oestradiol-17β and progesterone measured in serum and related to those in peritoneal fluid served to divide the cycle into two phases, i.e. the follicular and the luteal phase (Bouckaert et al., 1986b).

Concentrations of C-reactive protein, α₁-antitrypsin, acid-α₁-glycoprotein, α₂-macroglobulin, haptoglobin, complement factors C₁ and C₃, IgG, IgA and IgM were measured in the supernatant of the peritoneal fluid and in serum by means of a radial-immunodiffusion technique based on the radial diffusion and precipitation of a protein with its corresponding monospecific antiserum in an agar gel layer (M-Partigen and LC-partigen immunodiffusion plates: Behring Institut, Amsterdam, The Netherlands)(Mancini et al., 1965). The interassay variabilities (%) for the proteins that were analysed were 6.4 for C-reactive protein, 3.9 for α₁-antitrypsin, 2.3 for acid-α₁-glycoprotein, 7.5 for α₂-macroglobulin, 4.3 for haptoglobin, 5.5 for C₁-protein, 4.6 for C₃-protein, 2.5 for IgA, 2.3 for IgG, and 3.0 for IgM.

The ratio of peritoneal fluid concentration/serum concentration (p/s ratio) was determined for the individual proteins. Peritoneal fluid volume end the p/s ratios were compared between patients with and without endometriosis and between the follicular and the luteal phase of the cycle for patients with endometriosis and controls. The results were tested statistically by the Wilcoxon rank sum test for unpaired samples. Statistical significance was defined as P < 0.05. Spearman's rank correlation test was applied to test the correlation between the p/s ratio of the individual proteins and their molecular weight.

Results

At laparoscopy endometriosis was diagnosed in 25 patients (AFS score 1, N = 16; AFS score 2, N = 9). The controls were 45 patients without the disease. Based on

the information from serum and peritoneal fluid determinations of oestradiol-17β and progesterone, 6 patients in the endometriosis group were classified in the follicular and 19 in the luteal phase of the cycle. The figures for controls were 4 and 41 respectively.

C-reactive protein was below the level of detection (5 mg/l) in peritoneal fluid and serum in all patients studied.

In patients with endometriosis there was an increase of the peritoneal fluid volume in the luteal phase of the cycle (Table 4.1: P = 0.051). No significant differences were noted between patients with and without endometriosis for the ratio of individual proteins in peritoneal fluid and serum (Table 4.2). Values for these ratios in the follicular and luteal phase of the cycle are shown in Table 4.3. In patients with endometriosis only the IgG value differed significantly between the two phases of the cycle, but in the controls all the values except those for α1-antitrypsin, IgG and IgM were increased in the luteal phase of the cycle.

Correlating the results of the peritoneal fluid:serum ratio for the individual proteins with their molecular weights a significant inverse relationship was found in the endometriosis patients (N = 9, r = -0.93, P < 0.01) and in the controls (N = 9, r

= -0.93, P < 0.01 (Spearman’s rank correlation test): the higher the molecular weight of a given protein, the lower was its concentration in the peritoneal fluid (Table 4.4).

Discussion

Peritoneal fluid is mainly the result of ovarian exudation, while peritoneal exudation, follicular rupture and tubal secretion contribute only a small volume (Maathuis et al., 1978; Koninckx et al., 1980; Bouckaert et al., 1986a). The supposed inflammatory reaction secondary to peritoneal implants of endometriosis may cause an increased permeability of the subperitoneal capillaries, resulting in a change of the equilibrium between inflow and outflow of fluid across the peritoneal membrane, leading to an increased peritoneal fluid volume. Since we did not find such an increase, we suggest that the inflammatory reaction is not of such a degree that it gives rise to a significant change in peritoneal fluid volume. However, an increased production of peritoneal fluid could be counterbalanced by an increased reabsorption by the subperitoneal capillaries.

The acute-phase reaction, in which the concentration of certain plasma proteins increases, is recognized as a general and non-specific response to most forms of infective and non-infective inflammatory processes, cell and/or tissue necrosis, and malignant neoplasia. The acute-phase proteins are synthesized in the liver (Pepsy, 1981).

Circulating proteins reach the peritoneal cavity by exudation. The concentration of the various proteins in the peritoneal fluid depends predominantly on the hydrostatic pressure in the ovarian capillary network, the diameter of the endothelial gaps, the electrical charge of the individual proteins and their molecular weight (Bouck-
aert et al., 1986a). In endometriosis patients the concentration of acute-phase proteins, complement factors and immunoglobulins in the abdominal cavity may be increased secondary to changes in vascular permeability. Additionally some of the acute-phase proteins and complement factors are secreted by macrophages in an advanced stage of differentiation (Nathan, 1987).

To detect possible differences in the acute-phase response in peritoneal fluid between endometriosis patients and controls, it seems appropriate, in view of the above, to consider the ratio of the concentrations of the separate proteins in peritoneal fluid and serum. This ratio reflects the various sources of the peritoneal fluid proteins, i.e. exudation or in-situ production. Our earlier finding (Bouckaert et al., 1986a) of a significant inverse relationship between the molecular weight of the specific protein and its peritoneal fluid:serum ratio was confirmed in the control group. A comparable relationship was found for endometriosis patients. Retrograde menstruation, ovulation and, in endometriosis patients, cyclic shedding of peritoneal implants cause a continuously changing intraabdominal environment and thus possibly alter intraabdominal protein concentrations. When ratios for the specific proteins were compared between endometriosis patients and controls no significant differences were found, indicating a constant and equal exudation and/or in-situ production of these proteins in both groups. Apparently the intraabdominal protein concentration is not influenced to a great extent by the presence of peritoneal implants of endometriosis.

The ratios of the individual proteins in the follicular phase of the cycle in endometriosis patients in comparison to controls suggest a contribution from sources other than the ovaries, e.g. the peritoneum and the intraabdominal macrophages, reflecting an intraabdominal inflammatory reaction, secondary to peritoneal implants of endometriosis. The cycle dependent increase of protein exudation in the luteal phase of the cycle may outweigh the presumptive contribution of the peritoneal exudation and production by macrophages in endometriosis patients. Due to the low sample size (N = 4) the ratios of the follicular phase of control patients could be erroneously low and thus indirectly give the impression of a high ratio in the follicular phase of the endometriosis patients.

We conclude that endometriosis does not cause marked intraabdominal inflammatory changes. We base this on the lack of a significant increase of the peritoneal fluid volume and of the peritoneal fluid:serum ratios of the various proteins determined in patients with endometriosis compared to controls. If the presence of peritoneal implants of endometriosis lowers fecundity, the mechanism likely does not involve acute-phase protein synthesis.

Fibrinolytic properties of peritoneal fluid in endometriosis of women

(Gynecologic and Obstetric Investigation, accepted for publication)

Summary

A decreased intraabdominal fibrinolytic activity has been proposed as an etiological factor in the development of endometriosis. To test this hypothesis plasminogen, fibrinogen, α₂-antiplasmin, α₂-macroglobulin, plasminogen activator (t-PA) and its inhibitor (PAI) and the degradation products of fibrin were determined in the peritoneal fluid of 25 patients with and 45 patients without endometriosis. No significant difference was found for any of the parameters. Therefore, a role for the fibrinolytic system as an etiological factor in the development of endometriosis is unlikely. A high concentration of t-PA was found in comparison to normal blood levels, leading to a high concentration of fibrin degradation products in the peritoneal fluid, indicating an active system of intraabdominal fibrinolysis. A high concentration of fibrin degradation products further indicates the presence of fibrinogen and its turnover secondary to thrombin action.
Introduction

According to Sampson's theory on the pathogenesis of endometriosis, the disease develops secondary to transubal regurgitation and subsequent implantation of endometrial fragments on ovaries or peritoneum (Sampson, 1927). Alternatively, peritoneal irritation by retrograde menstruation may lead to endometriosis by the process of induction (Levander and Norman, 1955). Since retrograde menstruation occurs in most women regardless of the existence of endometriosis (Halme et al., 1984), other etiological factors must be present to allow development of endometriosis. Changes in cellular immunity and the luteinized unruptured follicle syndrome have been proposed as etiological factors (Steele et al., 1984, Brosens et al., 1978). Malick (1982) developed the hypothesis that a change in intraabdominal fibrinolysis could be etiologic with respect to the development of endometriosis. The capacity to lyse intraabdominal fibrin deposits, that develop secondary to peritoneal injury, is derived from plasminogen activators found within the lysozomal fraction of the mesothelial cells (Gervin et al., 1973). Plasminogen activator converts plasminogen to plasmin, which in turn degrades fibrin deposits. This has been associated with the prevention of adhesionformation (Buckman et al., 1976).

Malick (1982) suggested that a decreased intraabdominal plasminogen activator activity could be responsible for the development of endometriosis and the adhesions seen in this disease.

To test this hypothesis we studied the fibrinolytic properties of peritoneal fluid of patients with and without endometriosis. The major disadvantage of overall tests, like the fibrin plate method, as used by Malick (1982), is that the test finding is the resultant of the effects of several components and of their interactions. To gain more insight into the separate components of the fibrinolytic system, we decided to study plasminogen, fibrinogen, α2-antiplasmin and α2-macroglobulin, as well as the levels of plasminogen activator and its inhibitor and the degradation products of fibrin.

Materials and Methods

Peritoneal fluid (PF) was collected during laparoscopy in 70 patients from the pouch of Douglas and the vesicouterine space under direct vision as previously described (Bouckaert et al., 1986). The laparoscopies were planned in the early luteal phase of the menstrual cycle, based on information regarding the length of the previous cycles and the first day of the last menstrual period. The indication for laparoscopy was infertility in 40, abdominal pain in 9 and sterilisation in 21 patients. They all had regular cycles, ranging from 23 to 35 days. None of the patients had used oral contraceptives or ovulation inducing drugs or an intrauterine contraceptive device for the last
three months prior to the laparoscopy. Patients with occluded tubes were excluded. At laparoscopy all patients were carefully screened for the presence of endometriosis. The diagnosis was made on morphological grounds. Endometriosis was identified according to the classification of the American Fertility Society (AFS) (1979). The peritoneal fluid was collected in two tubes, a polystyrene one and a glass one. The first tube contained 0.2 ml citrate and was filled to 2 ml with PF. After centrifugation at 1000 g plasminogen, fibrinogen, $\alpha_2$-antiplasmin, $\alpha_2$-macroglobulin, fibrin degradation products (FDP), tissue plasminogen activator (t-PA) and tissue plasminogen activator inhibitor (PAI) were determined in the supernatant. Prior to induction of anaesthesia a 5-ml blood sample was drawn, centrifuged and the supernatant stored at -70°C. After centrifugation, the supernatant of the PF in the glass tube was used to determine progesterone and oestradiol-17$\beta$. In the serum progesterone and oestradiol-17$\beta$ were determined. The values of progesterone and oestradiol-17$\beta$ measured in serum as related to those in peritoneal fluid, divided the cycle into two phases, i.e. the follicular and the luteal phase (Bouckaert et al., 1986). Fibrinogen was measured as described by Clauss (1957), using a Schnitger and Gross coagulometer. Plasminogen and $\alpha_2$-macroglobulin were assayed by an immunochromatographic method based upon radial immunodiffusion using M-Partigen plates (Hoechst-Behring). The Coatest antiplasmin (Kabi Vitrum Diagnostica) was used for the measurement of $\alpha_2$-antiplasmin by using the chromogenic substrate H$_2$O$_2$-Val-Leu-Lys-p-nitroanilide (S-2251, Kabi Vitrum Diagnostica).

The fibrin degradation products were measured using the D-dimer test (Ortho Corporation). The D-dimer test is a specific semi-quantitative beads test for the detection of degradation products of fibrin only, and not of fibrinogen. t-PA as well as PAI activity were quantitated by measuring the enzymatic activity of the formed plasmin in the presence of fibrinogen fragments with a synthetic substrate. The substrate used was S-2251 (Kabi Vitrum Diagnostica) (Drapier et al., 1979; Verheijen et al., 1982).

To identify patients with subclinical inflammatory pelvic disease C-reactive protein (CRP) was determined in PF and serum, using single radial immunodiffusion (Mancini et al., 1965).

Comparisons of the various parameters were made between patients with and without endometriosis. The results were tested statistically by the Wilcoxon rank sum test for unpaired samples. Statistical significance was defined as $P < 0.05$.

Results

At laparoscopy endometriosis was diagnosed in 25 patients (AFS score 1, N = 16; AFS score 2, N = 9). Forty five patients without the disease served as controls. Based on serum and PF determinations of progesterone and oestradiol-17$\beta$, 6 patients

in the endometriosis group were classified in the follicular and 19 in the luteal phase of the cycle. The figures for controls were 4 and 41 respectively. CRP was below the level of detection in all PF and serum specimens, indicating the absence of an acute pelvic infection in all patients. Table 5.1 shows the results of the parameters determined comparing patients with and without endometriosis. The results are given as median values and range. No significant difference was found between the two groups for any of the parameters.

Discussion

Malick (1982) measured fibrinolytic activity using a modification of the fibrin plate method of Astrup & Müllertz (1952). The lysis of the fibrin plates, caused by uterine serosal tissue of patients with and without endometriosis, was less pronounced in the samples of endometriosis patients as compared to controls. She concluded that a decreased coelomic plasminogen activator activity, acquired or inherited, in con-
junction with retrograde menstruation is etiologic with respect to the development of endometriosis and associated adhesions. This hypothesis seemed quite attractive, the more since the fibrinolytic system has been associated with intraabdominal adhesion formation (Buckman et al., 1976). Unfortunately, Malick (1982) based this hypothesis on not more than two tissue samples of only one patient with endometriosis. Using the fibrin plate method Pattinson et al. (1981) did not find detectable levels of plasminogen activator activity in PF of patients with and without endometriosis. Since fibrinogen degradation products and plasminogen were present in the samples of PF, they concluded that fibrinolytic activity was present in the PF of endometriosis patients and controls. Batzofin et al. (1985) did not find any differences in PF plasminogen activator activity comparing endometriosis patients with controls, neither did they, comparing patients with and without adhesions. They used a method based on the degradation of 125I-labeled fibrin by plasmin (Strickland and Beers, 1976). Although this method is a very sensitive one, the results may be obscured by plasmin inactivation or by the presence of inhibitors (Drapier et al., 1979). Moreover, this method does not distinguish between urokinase and t-PA, the two major physiological plasminogen activators (Bachman and Kuithof, 1984). The fibrin plate method to assess the plasminogen activator activity, as used by Pattinson et al. (1981) and Malick (1982), possesses the same disadvantages (Bachman and Kuithof, 1984).

The above-mentioned studies assess total fibrinolytic activity by integrative assays of fibrinolysis. In our study we assessed plasminogen activator activity by measuring both t-PA and its fast inhibitor, PAI. Additionally, the end product of plasminogen activation, i.e. fibrin degradation products, and not a mixture of fibrinogen and fibrin degradation products, were determined. Finally, the precursors of plasmin and fibrin and the inhibitors of plasmin were determined.

As shown in Table 5.1 the levels of the precursors of plasmin and fibrin, plasminogen and fibrinogen, were not different in patients with endometriosis and in controls. Two major inhibitors of the fibrinolytic system, α2-antiplasmin and α2-macroglobulin, were not different in both groups either. Comparing patients with and without endometriosis we did not find significantly different levels of plasminogen activator and its inhibitor. Fibrin degradation products are the final result of fibrinolysis. The D-dimer test we used is specific for the degradation products of fibrin. Again no significantly different results were obtained in either group of patients.

From these results we conclude that no major differences in the intraabdominal fibrinolytic system as measured in the PF are discernable between patients with and without endometriosis. These results are in agreement with the results of the study of Batzofin et al. (1985).

The results of our study show that an active fibrinolytic system exists in the abdominal cavity. Until now this intraabdominal fibrinolytic activity was assumed to be present, based on the lack of clot formation in peritoneal fluid, on the presence of fibrinogen degradation products and the presence of high levels of plasminogen in
peritoneal fluid and on the lysis of fibrin plates by PF (Pattinson et al., 1981; Bazoñ, et al., 1985). The concentration of fibrin degradation products in the PF of the patients under investigation and of the controls was higher than the levels normally found in plasma (< 200 mg/ml), indicating a high intraabdominal fibrinolytic activity. t-PA levels in plasma measured by the above described method in our laboratory are below 0.1 IU/ml. t-PA levels in the PF in our patients, with and without endometriosis, were manifold higher. This indicates either an active production and secretion of t-PA in the abdominal cavity or a low PAI level and supports the above-mentioned assumptions that an active fibrinolytic system exists in the abdominal cavity.

Plasminogen activator inhibitor and plasminogen activator as found in PF presumably have various sources. As recently reviewed (Sprengers and Kuft, 1987) PA-inhibitors can be classified in at least three immunologically different groups. Sources of PA-inhibitors include endothelial cells, granulosa cells, blood platelets, vascular smooth muscle cells, macrophages and placenta. As reviewed by Bachmann and Kruithof (1984) plasminogen activators can be extracted from many animal and human tissues, including endometrium, mesothelial cells, vascular endothelium and stimulated peritoneal macrophages. Åstedt and Nordenskjöld (1984) suggested ectopic endometrium as a source of plasminogen activators, since they found increased concentrations of plasminogen activators in PF of patients with endometriosis. In contrast, Ohtsuka (1980) found a decreased concentration of plasminogen activator activity at tissue level in endometriotic lesions. Since ovulation is at least in part a proteolytic enzyme mediated event (Strickland and Beers, 1976), the content of the follicle can be considered as another important source of plasminogen activator.

We conclude that there is an active system of intraabdominal fibrinolysis, as shown by a higher concentration of t-PA in PF than in blood. A high concentration of fibrin degradation products in the peritoneal fluid ensues.

The intraabdominal fibrinolytic system as measured by the concentrations in PF of plasminogen, fibrinogen, α2-antiplasmin, α2-macroglobulin, t-PA, PAI and fibrin degradation products is not different in women with endometriosis as compared to women without the disease. Therefore a role for the fibrinolytic system as an etiological factor in the development of endometriosis is unlikely. To further substantiate this conclusion, studies on tissue level yet have to exclude more subtle differences in fibrinolysis.

Functional aspects of peritoneal macrophages in endometriosis of women

G.A.J. Danselman, M.G.R. Hendrix, P.X.J.M. Bouckaert, J.L.H. Evers
(with permission)

Summary

Peritoneal fluid was collected in the periovulatory phase of the cycle from 25 women undergoing laparoscopy. Endometriosis was diagnosed in 13 patients (AFS score 1, N = 9; AFS score 2, N = 4) and 12 patients without endometriosis served as controls. In endometriosis patients the total peritoneal fluid cell number and cell concentration was significantly higher than in controls, indicating peritoneal irritation by endometrial implants.

Peritoneal fluid macrophages in patients with endometriosis showed significantly increased erythrophagocytosis and lower chemiluminescence than in controls suggesting an advanced differentiation of the macrophages in endometriosis patients. The macrophages in this stage of differentiation may interfere with gametes and embryos and thus contribute to endometriosis-associated subfertility.
Introduction

Although the association between endometriosis and infertility is accepted, its nature is far from being understood. In recent years peritoneal fluid and its cellular constituents have received considerable attention in the process of elucidating the causes of infertility; peritoneal macrophages are particularly supposed to play an important role in endometriosis-related subfertility (Haney et al., 1981; Badawy et al., 1984; Halme et al., 1982; Olive et al., 1985). Phagocytosis of spermatozoa by peritoneal macrophages has been reported to be increased in endometriosis patients (Muscato et al., 1982).

In this study we determined the cell number of the peritoneal fluid and functional aspects of peritoneal macrophages, erythrophagocytosis and chemiluminescence, reflecting the level of differentiation of the macrophages (Cohn, 1978).

Materials and Methods

Patients, fluid collection and analysis
Peritoneal fluid was collected in the periovulatory phase of the cycle from 25 women undergoing laparoscopy. The indication for laparoscopy was infertility (N = 16), abdominal pain (N = 3) and sterilization (N = 6). All patients had regular cycles varying in duration between 23 and 35 days. They had not used oral contraceptives or ovulation inducing drugs or an intrauterine contraceptive device for at least 3 months before the laparoscopy. Patients with occluded Fallopian tubes were excluded. At laparoscopy the presence or absence of endometriosis was recorded. Endometriosis was classified according to the classification of the American Fertility Society (1979).

Peritoneal fluid was collected under direct vision from the pouch of Douglas and the vesicouterine space as described by Bouckaert et al. (1986). Care was taken to collect all peritoneal fluid. The peritoneal fluid was collected in glass tubes, 1.5 mg tetra sodium ethylene diamine tetraacetic acid (EDTA)/ml were added as anticoagulant and the tubes were stored on ice.

Before induction of anaesthesia a 5-ml blood sample was withdrawn, allowed to clot and centrifuged. The supernatant serum was stored at -70°C.

The periovulatory phase of the cycle in which the laparoscopy was to be performed was determined using knowledge of the length of the previous cycles and the first day of the last menstrual period. The concentrations of oestradiol-17β and progesterone measured in serum and peritoneal fluid allowed further subdivision of the periovulatory phase into the follicular and luteal phases (Bouckaert et al., 1986). To identify patients with subclinical inflammatory pelvic disease C-reactive protein
was measured in peritoneal fluid and serum, using single radial immunodiffusion (Mancini et al., 1965).
The peritoneal fluid was centrifuged at 350 g at 4°C for 10 min to harvest the peritoneal cells. The supernatants were collected and stored at -70°C. The pellet was resuspended in Hank’s balanced salt solution (HBSS). Peritoneal cells were counted and the viability determined by trypan blue exclusion. Cells were identified after May-Gruenewald-Giemsa fixation and staining from morphological criteria such as polymorphous nuclear cells (PMN), lymphocytes or macrophages.

**Erythrophagocytosis and chemiluminescence**

Fc mediated erythrophagocytosis (sheep red blood cell phagocytosis = SRBC phagocytosis) was measured as described before (Hendrix et al., 1986). In short, peritoneal cell monolayers were prepared in 16-mm wells on 13-mm round glass coverslips by incubating for 1 h at 37°C. After adherence, antibody-coated sheep erythrocytes were added to the monolayers and incubated for 1 h at 37°C. Non-adherent erythrocytes were subsequently removed by vigorous washing with phosphate buffered saline (PBS). Each coverslip was then incubated for 10 min in a 0.85% (w/v) ammonium chloride (Merck) solution to lyse non-internalized erythrocytes. After fixation the number of macrophages containing no erythrocytes were counted by phase-contrast microscopy. At least 200 cells were counted for each experiment. The results are expressed as the percentage of peritoneal cells containing at least one erythrocyte.

Chemiluminescence was measured with a lumino-aggregometer, using opsonized zymosan as stimulating agent, as previously described (Hendrix et al., 1986). In short, opsonized zymosan was prepared by boiling 8 g zymosan (Sigma Chemical Co., St Louis, Missouri, USA) for 30 min in 2 ml PBS, centrifuging at 350 g for 10 min and resuspending in 200 μl normal human AB serum. After incubation for 30 min at 37°C the solution was centrifuged again and resuspended in HBSS to a final concentration of 4 mg/ml. Chemiluminescence was evaluated by introducing 0.1 ml of a cell suspension containing 2x10⁶ peritoneal cells, 0.1 ml HBSS + 0.1% (w/v) gelatin (Difco, Detroit, Michigan, USA), 0.1 ml luminol (10⁻⁶ M) (Lumac, Landgraaf, The Netherlands) and 0.1 ml 50% human AB serum in a silicon-coated glass vial, and placing it in the Chronolog. When the background light emission became constant, 0.1 ml of the appropriate zymosan suspension was added and the photo-emission was scored continuously during the first 10 min of the reaction. The chemiluminescence response was recorded in duplicate for each experiment. Results are shown as a relative value (units) for the light emission calculated from the total area under the curve during the first 10 min of the chemiluminescence response.

**Analyses**

Comparisons were made between patients with endometriosis and patients without the disease, for the following values: total peritoneal cell number, cell number per

Statistical analysis was performed using the Wilcoxon rank sum test for non-paired samples.

Results

At laparoscopy, 13 patients were found to have endometriosis (Score 1, N = 9; Score 2, N = 4; American Fertility Society, 1979); 12 patients without endometriosis served as controls. Based on the oestradiol-17β and progesterone concentrations in peritoneal fluid and serum (Bouckaert et al., 1986), 5 patients in the endometriosis group were classified as being in the follicular and 8 as being in the luteal phase of the cycle. The figures for controls were 2 and 10 respectively. Values of C-reactive protein were below the level of detection in all peritoneal fluid and serum specimens.

As shown in Table 6.1, the median value of the total cell number and the median value of the cell number per ml peritoneal fluid in endometriosis patients were higher than in controls, both differences were statistically significant (P < 0.05). The viability of the cells and the percentage of macrophages in the differential count were not significantly different in the two groups (Table 6.2). Table 6.3 shows the results of the sheep RBC phagocytosis and of the chemiluminescence of peritoneal cells in endometriosis and controls. A statistically significant difference in SRBC phagocytosis existed between endometriosis patients and controls (P < 0.0001). The lower level of chemiluminescence in endometriosis patients also was statistically significant (P < 0.001).

Discussion

Increased total peritoneal fluid cell numbers and cell concentrations, with a percentage of macrophages of 80% and higher have repeatedly been reported in the literature in patients with endometriosis as compared to controls, although the differences were not always statistically significant (Haney et al., 1981; Badawy et al., 1981; Halme et al., 1982, 1984; Olive et al., 1985). In the present study we confirmed the increased number and the increased concentration of peritoneal cells in patients with endometriosis as compared to controls. The peritoneal cavity is normally populated by resident macrophages. Secondary to several stimuli, including shedding of endometrial tissue in addition to ovulation and retrograde menstruation, monocytes are attracted from the bloodstream and convert to differentiated macrophages,
leading to an increased concentration of peritoneal cells. An acute inflammatory process will change the peritoneal cell number considerably. The finding in our study that C-reactive protein was below the level of detection in peritoneal fluid and in serum in patients with endometriosis and in the control group indicates that there was no acute intraperitoneal inflammatory process in either group at the time of the laparoscopy (Lehtinen et al., 1986).

The phagocytic capacity of peritoneal macrophages measured by the uptake of opsonized zymosan has been reported to be comparable in endometriosis patients and controls (Halme et al., 1984). We found an increased phagocytosis of sheep RBCs by macrophages recovered from the peritoneal fluid of patients with endometriosis as compared to controls. Viability and percentage of macrophages in peritoneal cells were the same in each group (Table 6.2). The increased ability of peritoneal macrophages to phagocytose antibody-coated particles (sheep RBCs) supports the findings of London et al. (1985) concerning macrophage-mediated sperm killing as a possible cause of subfertility.

A remarkable finding of the present investigation was the significantly reduced chemiluminescence measured in peritoneal macrophages of endometriosis patients. The dissociation that we found between an increased phagocytosis and a reduced chemiluminescence of macrophages in endometriosis patients compared with controls possibly finds its explanation in subsequent degrees of differentiation of the peritoneal macrophages. In recent years it has become clear that after stimulation macrophages undergo changes in metabolism and differentiate in a stepwise fashion (Cohn, 1978; Yamamoto and Johnston, 1984; Johnson et al., 1986). Following this concept the levels of phagocytosis and chemiluminescence measured in control patients represent a baseline steady state level. The enhanced phagocytosis and the diminished chemiluminescence in endometriosis patients indicate a next step in differentiation, the macrophages are engaged in phagocytosis and have left the stage of $O_2^-$ production.

The concept of a more advanced stage of differentiation of peritoneal macrophages in patients with endometriosis is supported by two reports. Fakih et al. (1987) reported on the presence of interleukin-1, a protein produced by differentiated peritoneal macrophages and a mediator of host responses, in the peritoneal fluid of patients with endometriosis and not in that of controls without the disease. Halme et al. (1987), extending earlier observations (Halme et al., 1984), described the existence of larger, more mature macrophages in peritoneal fluid of patients with endometriosis.

In conclusion, we found increased sheep RBC phagocytosis and a decreased level of chemiluminescence of peritoneal macrophages in patients with endometriosis compared to controls. This is consistent with an advanced level of differentiation of peritoneal macrophages in patients with endometriosis.

These macrophages may interfere with gametes and pre-implantation embryos and thus contribute to endometriosis-associated subfertility.

Chapter 7

A rabbit model of endometriosis

(Gynecologic and Obstetric Investigation, accepted for publication)

Summary

Since not all problems in endometriosis can be studied in the human, there is need of an animal model. We transplanted endometrial tissue of the rabbit into the peritoneal cavity and studied the changes after 12 weeks. At that time endometrial implants in the rabbit had become cystic structures. The macroscopic and histological appearance was consistent with endometriosis. Hormonal supplementation turned out to be not necessary. Microsurgical techniques prevented the formation of tubo-ovarian adhesions. This makes the rabbit model suitable to study the influence of endometrial implants on fertility.
Introduction

Although endometriosis occurs spontaneously in some subhuman primates, it has to be considered a basically human condition. The low prevalence of spontaneous endometriosis in monkeys curtails their use in endometriosis research (MacKenzie, 1975). In the human, ethical problems restrict the study of various unsolved issues regarding etiology, treatment modalities and the relation between endometriosis and infertility. If endometriosis is regarded as a result of retrograde menstruation - whether endometrial fragments actually implant (Sampson, 1940) or liberate substances that induce the peritoneum to change into endometriosis (Levander and Normann, 1955; Merrill, 1966) - the surgical implantation of pieces of endometrium onto the peritoneum of animals may be used as a model to study the above-mentioned problems.

We report on the use of endometrial transplants in the rabbit to study the relationship between infertility and endometriosis.

Materials and Methods

Virgin female Dutch belted rabbits were used. Animal handling has been described previously (Land, 1985). Before surgery each doe received 125 mg of ampicillin prophylactically by intravenous injection. Anaesthesia was induced with 0.2 mg atropine/kg and 0.5 ml Hypnorm/kg (10 mg fluanizone and 0.2 mg phentanyl per ml, Duphar, Amsterdam) intramuscularly. As soon as adequate anaesthesia was achieved, each doe was intubated with an endotracheal tube. A mixture of halothane (0.5-1.0%), oxygen (1 litre/min) and nitrous oxide (2 litre/min) was given through a closed loop inhalation anaesthesia system (infant ventilator, MK2, Keuskamp, Amsterdam). A lower abdominal midline incision was used to expose the viscera and the internal genitals. To prevent adhesion formation, care was taken to avoid unnecessary tissue handling, microsurgical principles were observed, the area was kept moist during the entire procedure and nonresorbable 6.0 Prolene sutures (Ethicon, Somerville, NJ) were used. In 50 rabbits a 1-cm segment of the right uterine horn as well as adipose tissue from the juxta-uterine fat was resected. After resection, the uterine horn was reanastomosed and the defect in the fat tissue closed by microsurgical methods. In 25 rabbits (Experimental Group = Group E) the resected uterine horn was opened longitudinally and divided into four 3x3 mm parts. These pieces of uterine tissue (consisting of endometrium, muscularis and serosa) were sutured onto the peritoneum at the right lateral abdominal wall, adjacent to the uterus and ovary, with the serosal side of the uterine tissue facing the peritoneum, and the endometrium facing the peritoneal cavity. Figure 7.1 shows the four

transplanted pieces of endometrial tissue. In 25 rabbits (Control group = Group C) the fat was divided into four equal parts and sutured onto the peritoneum in a comparable way. In Group E the fat tissue was discarded and in Group C the uterine tissue was discarded. The abdominal wall was closed in two layers with evertimg interrupted sutures. The fat tissue was transplanted in a similar way. The animals did not receive any hormonal supplementation either before or after surgery. After a period of 12 weeks the does were sacrificed. Anaesthesia was induced with 0.5 mg xylazine/kg (Rompun: Bayer, Leverkusen, West Germany) and 0.4 ml ketamine/kg (Ketaset: Bristol Laboratories, New York) by intramuscular injection. An overdose of pentobarbitone sodium was administered intravenously and laparotomy was performed. Adhesions were scored and the gross morphology of the implants was recorded. All implants were excised, fixed overnight at room temperature in a mixture of alcohol (100%), glacial acetic acid and formaldehyde (40%) 15:1:4 (v/v), and routinely paraffin embedded. Serial 4 micron sections were cut and haematoxilin-eosin-stained sections of all endometrial and fat implants were examined.

Results

All rabbits survived the first laparotomy and the 12 week recovery period. In all rabbits of Group E cystic structures varying in diameter between 5 and 15 mm were found in place of the endometrial implants. The cysts were filled with a clear yellow or brownish fluid (Figure 7.2). Ovaries and oviducts were free of adhesions in all animals. Light microscopy examination of the implants revealed endometrial glands surrounded by well vascularized stroma (Figures 7.3a and 7.3b). The cysts were lined by flattened epithelium at the side facing the peritoneal cavity. At the abdominal wall side, high cylindric epithelium was seen. The lumen of the cysts contained epithelial cells and erythrocytes (Figure 7.4a). The cysts were covered by mesothelial cells (Figure 7.4b). All fat transplants in group C only showed fat tissue, both on macroscopic and histological examination.

Discussion

The ability of endometrial tissue to proliferate after autotransplantation to various ectopic locations has been documented in the monkey, the rat and the rabbit (Schenken and Asch, 1980; Schenken et al., 1984; Vernon and Wilson, 1985). In
studying the effects of endometriosis on fertility the three animal models all have
their pros and cons. The main advantage of the monkey model is the fact that the
menstrual cycle and the gross and histological appearance of the disease are similar
to those in the human. The main disadvantages are the high cost and the difficulties
in animal handling. The rat model offers a cheap, cycling animal with 70 to 80 es-
trous cycles a year, although with a very short luteal phase. The main disadvantage
of the use of the rat model to study the influence of endometriosis on fertility, is
that the rat ovary is surrounded by a tight bursa, which may isolate it from the sur-
rounding peritoneal environment. Consequently peritoneal fluid constituents, af-
fected by the presence of endometriosis, may not be able to exert their (possibly deleterious) effects on the developing follicle, the mechanism of ovulation, the pick-
up function of the oviduct, the gametes, fertilization and the early embryo.
The advantages of the use of the rabbit model in studying endometriosis related in-
fertility are the low cost and the relative ease and high success rate of transplanting
endometrial tissue. Normal patterns of ovulation, fertilization, tubal transport and
early embryonic development have been thoroughly studied in the rabbit (Land,
1985). The double uterus of the rabbit allows for altering one side and for studying
the effect of these alterations, both on the ipsilateral side and on the untouched con-
tralateral side. The main disadvantage of the rabbit model is the fact that it is a
reflex ovulator and as such does not have reproductive cycles comparable to the hu-
man.
We showed that small pieces of the uterine wall, consisting of serosa, muscularis and
mucosa, after transplantation onto the peritoneum were replaced by cystic struc-
tures that are morphologically consistent with endometriosis. Histology confirmed
these endometriosis-like changes. Schenken and Asch (1980) and Donnez et al.
(1987) used supplementation of estrogens prior to and after the transplantation of
endometrium in the rabbit. In these studies (Schenken and Asch, 1980; Donnez et
al., 1987) hormonal supplementation rather than endometrial implants may have in-
fluenced early embryonic development. In our study supplementation of estrogens
did not appear to be necessary for the development and growth of the implants,
although the animals lack a menstrual cycle. This is in accordance with the recent
findings of Hahn et al. (1985).
An additional observation was that it did not appear to be necessary to dissect the
endometrium from the underlying myometrium, a procedure adopted by others using
this same model (Schenken and Asch, 1980; Hahn et al., 1985). Endometrial
glands require stromal cells to implant and grow (Zamah et al., 1984). In menstruat-
ing species the stromal layer is sloughed off during menstruation together with the
endometrial layer, in contrast to estrous animals, where the stromal layer remains
in place. This may explain the lack of spontaneous endometriosis in estrous animals
(Vernon and Wilson, 1985).
The increase in size of the original implants to the size of the implants found after
12 weeks, the formation of cysts, the proliferative changes in the glandular epitheli-
um and the vascularization are indicative of active growth of endometrial tissue.
Conceivably, these endometrial transplants can have an effect on the composition of peritoneal fluid. Hahn et al. (1986) showed that the fertility of rabbits was impaired, after they had received peritoneal fluid from rabbits with induced endometriosis.

In the 25 rabbits with endometrial transplants and in the 25 rabbits with fat transplants adhesions were confined to the uterine anastomosis and the small and large bowel. Ovaries and oviducts were completely free of even filmy adhesions. This is in contrast with other studies. It is therefore not clear whether the disturbances in early embryonic development that were found by others were caused by the adhesions involving ovaries and oviducts, or by the endometrial implants per se (Schenken and Asch, 1980; Schenken and Walters, 1986; Donnez et al., 1987). It has been suggested that adhesions may affect follicle growth and ovulation (Hamilton et al., 1986). Postoperative adhesion formation rather than endometrial implants therefore may be responsible for the observations as reported in the above-mentioned studies (Schenken and Asch, 1980; Schenken and Walters, 1986; Donnez et al., 1987).

In summary, endometrial implants in the rabbit offer a suitable model to study the influence of minimal and mild endometriosis on fertility, provided that meticulous surgical techniques are applied in order to prevent the formation of tubo-ovarian adhesions.

Effect of endometriosis on ovulation, ovum pickup, fertilization and tubal transport in the rabbit

G.A.J. Duuselman, J.A. Land, P.X.J.M. Bouckaert, J.L.H. Evers
(with permission)

Summary

In 25 rabbits (Group E) endometrium from the right uterine horn was transplanted onto the peritoneum. In 25 rabbits (Group C) fat was transplanted. After a recovery period of 12 weeks the does were mated, and killed 24 h later. In Group E the implants had changed into cysts of 5 to 15 mm in diameter. Histological examination revealed endometrial glands and stroma in every specimen. Periadnexal adhesions did not develop in any animal. No differences between Groups E and C were found in the number of corpora lutea, the recovery rate, the fertilization rate and the transport of fertilized ova. These findings indicate that endometrial implants in the rabbit have no influence on the ovulatory mechanism, the pickup function of the oviduct, the fertilization rate or on the transport of fertilized ova. Taking into account the restrictions of a rabbit model, it is suggested that the decreased fecundity in mild endometriosis in the human may be caused by disturbances in postfertilization events, i.e. development of the preimplantation embryo or implantation.
Introduction

Patients with mild endometriosis have a monthly fecundity rate which is considerably below that of the general population (Olive and Haney, 1986). The reasons for this decreased fecundity, in particular when Fallopian tubes and ovaries are free of adhesions, remain unclear. Disturbances in folliculogenesis (Rönnberg et al., 1984; Wardle et al., 1985), ovulation (Soules et al., 1976; Brosens et al., 1978; Lesorgen et al., 1984), ovum pickup by the Fallopian tubes (Werlin et al., 1984; Sugimami et al., 1986), fertilization (Wardle et al., 1985) and implantation (Chillick et al., 1985) all have been suggested as a cause. Changes in the peritoneal milieu secondary to endometrial implants might cause these disturbances. There is evidence for an increased number of more active peritoneal macrophages in patients with endometriosis (review by Berger and Rock, 1985). Prostaglandins and proteolytic enzymes produced by macrophages might cause ovulatory dysfunction and altered tubal function (ovum pickup and transport). Altered tubal transport of the fertilized ovum can lead to an untimely arrival in the uterine cavity with subsequent implantation problems. The enhanced activity of the macrophage population may affect fertilization and implantation by influencing the immune system and by phagocytosis. Hahn et al. (1986) have reported that the decrease in fecundity, which they observed in rabbits with endometrial implants, was due to implantation failure. To study possible causes of subfertility in endometriosis, we investigated events in the periovulatory period, i.e. ovulation, ovum-pickup, fertilization and tubal transport of fertilized ova in rabbits with mild endometriosis.

Materials and Methods

Virgin Dutch belted rabbits were used. The 50 does were caged individually at 20°C with a photoperiod of 12 h light: 12 h dark. They were fed 150 g of rabbit chow daily and allowed water ad libitum. Before surgery each doe received 125 mg ampicillin prophylactically by intravenous injection. Anaesthesia was induced with 0.2 mg atropine/kg and 0.5 ml Hypnorm/kg (10 mg fluanizone and 0.2 mg phentanyi per ml: Duphar, Amsterdam, The Netherlands) intramuscularly. As soon as anaesthesia was achieved, each doe was intubated with an endotracheal tube. A mixture of halothane (0.5-1.0%), oxygen (1 litre/min) and nitrous oxide (2 litre/min) was given through a closed loop inhalation anaesthesia system (infant ventilator, MK2; Keuskamp Amsterdam, The Netherlands).

In all 50 rabbits a 1-cm segment of the right uterine horn as well as adipose tissue from the juxta-uterine fat was resected. After resection, the uterine horn was reanastomosed and the defect in the fat tissue closed by microsurgical methods. In
25 rabbits (Group E) the resected uterine horn was opened longitudinally and divided into four equal parts. These pieces of uterine tissue (consisting of endometrium, muscularis and serosa) were sutured onto the peritoneum at the right lateral abdominal wall, adjacent to uterus and ovary, with the serosal side of the uterine tissue facing the peritoneum, and the endometrium facing the peritoneal cavity, using 6.0 Prolene (Ethicon, Sommerville, NJ, USA). In 25 rabbits (Group C) the fat was divided into four equal parts and sutured onto the peritoneum in a comparable way. In Group E the fat tissue was discarded and in Group C the uterine tissue was discarded. The abdominal wall was closed in two layers with everting interrupted sutures. After a recovery period of 12 weeks the does were mated with a buck of proven fertility. To ensure and synchronize ovulation the does were given 125 i.u. hCG (Pregnyl: Organon, Oss, The Netherlands). The does were killed 24 h after mating, i.e. 12 h after ovulation (Harper, 1961). Anaesthesia was induced with 0.5 mg xylazine/kg (Rompun: Bayer, Leverkusen, West Germany) and 0.4 ml ketamine/kg (Ketaset: Bristol Laboratories, Syracuse, NY, USA) by intramuscular injection. An overdose of pentobarbitone sodium was administered intravenously and laparotomy was performed.

The abdominal cavity was carefully inspected for adhesions. The adhesions were scored, considering both extent and type of adhesions, as absent, mild (filmy adhesions) or moderate (dense adhesions). Adhesions from bladderfat, intestines and uterus to the endometrial implants were considered to have less consequences for fertility, than adhesions from ovaries and oviducts to endometrial implants.

The implants were excised for histological examination. The patency of the right reanastomosed uterine horn was tested. The ovaries and oviducts were excised. The ovaries were examined under a stereomicroscope (Wild M8) in order to count the number of corpora lutea in each ovary. The oviducts were divided into three parts representing the ampullary segment, the ampullary-isthmic junction and the isthmic segment. The three segments of both oviducts were flushed with 5 ml HEPES-buffered Whittingham’s T6 culture medium adjusted to pH 7.4 (Quinn et al., 1984). The flushings were checked for the presence of ova and embryos under a stereomicroscope (Wild M8). The numbers of fertilized ova and the segment from which they were retrieved were noted. From these data the tubal transport index 24 hours after mating was determined. The recovery rate, the fertilization rate and the tubal transport index were determined for each oviduct separately. Criteria for fertilization were the presence of spermatozoa in the perivitelline space, the presence of two polar bodies, the presence of two pronuclei, or cleavage. The results obtained were compared between the right and left oviducts in each group, and between the right oviducts and the left oviducts for Groups C and E. Statistical analysis was performed using the Wilcoxon rank sum test for paired samples comparing right and left sides. The Wilcoxon rank sum test for unpaired samples was used to compare Groups C and E.

Results

The mean duration of the operation was 53 ± 8 min in Group E and 51 ± 6 min in Group C. Bodyweights at autopsy were 2981 ± 212 g in Group E and 2896 ± 338 g in Group C (P > 0.05).

In all rabbits of Group E, the implants of the uterine tissue appeared to have developed into cysts filled with clear yellow or dark brown fluid. The diameter of the cysts ranged from 5 to 15 mm. Histological examination revealed endometrial glands and stroma in every specimen. In Group C the fat tissue had not changed since the operation and no endometrial tissue had developed.

In Group E rabbits adhesions were absent in 4 animals, mild in 8 (only filmy adhesions) and moderate in 13 (dense adhesions). The equivalent figures for Group C does were 17 absent, 6 mild and 2 moderate (P < 0.001, Chi-square test). However, the ovaries and oviducts were completely free of adhesions in every animal in both groups. The reanastomosed uterine horns were patent in every animal. As shown
in Table 8.1, the number of corpora lutea, the recovery rates and the fertilization rates did not differ significantly when the results obtained from the right sides of the animals were compared to those from the untouched left sides for rabbits in Groups E and C. In the flushings of 4 oviducts no fertilized ova were found. There were also no differences in tubal transport index for the right and left sides of rabbits in Groups C and E or between groups.

Comparison of animals with no adhesions to animals with mild adhesions and animals with moderate adhesions in Groups E and C showed no differences regarding number of corpora lutea, recovery rate, fertilization rate and tubal transport of fertilized ova.

Discussion

In rabbits, Schenken and Asch (1980) found a 50% decrease in fertility rate in rabbits with surgically induced endometriosis. The decrease in fertility was concluded to be due to failure of ovulation which was, according to the authors, not related to adhesions. However, 4 out of 5 rabbits with adhesions in their study did not ovulate. A significantly reduced ovulation rate in rabbits with endometriosis confirmed these findings (Schenken and Walters, 1986). The fertilization rates were not significantly different between groups of rabbits with and without endometrial implants, but the recovery rate in the endometriosis group was severely reduced (Schenken and Walters, 1986). This reduced recovery rate was considered to be caused by ovarian or fimbrial adhesions. Werlin et al. (1984) found reduced ovum recovery rates in monkeys with induced endometriosis when adhesions involved the fimbriae and ampulla. Schenken et al. (1984) reported a reduced incidence of ovulatory cycles in monkeys with moderate and severe endometriosis, in contrast to animals with microscopic and mild endometriosis, in which the incidence of ovulatory cycles was not different from control animals. These results are in agreement with the findings of our study: there was no difference in number of corpora lutea in rabbits with endometrial implants, but without adnexal adhesions, compared to control animals. Because of the absence of adnexal adhesions the endometrial implants in our study might mimic more closely the stages of minimal and mild endometriosis in the human.

The recovery rates of embryos in our study did not differ between the groups studied and suggest an adequate pickup function of the oviducts in all animals. The tubo-ovarian relationship, considered to be critical to ovum pickup, was not disturbed, presumably because of the absence of periadnexal adhesions. Therefore, the differences observed by previous investigators (Schenken and Asch, 1980; Schenken et al, 1984; Werlin et al, 1984; Schenken and Walters, 1986) might have been due to imperfect surgical technique. We have demonstrated, by applying meticulous
microsurgical techniques, that endometrial implants per se do not influence the recovery rate in rabbits. However, the recovery rate exceeded 100% for one or both sides. If the cumulative recovery rate for both sides is 100%, transmigration of ova from one ovary to the contralateral oviduct had presumably occurred, but if the recovery rate at both sides is over 100%, poly-ovulation or undercounting of corpora lutea may have been the cause. Undercounting was reduced to a minimum in our study by inspecting the ovaries for newly ruptured follicles under a stereomicroscope. Polyovular follicular development has been described for rabbits (Adams, 1960; Al-Mufti et al., 1988).

From in-vitro fertilization studies conflicting data have been reported on the fertilization of ova recovered in endometriosis patients. Normal fertilization rates have been found in patients with mild endometriosis (Chilik et al., 1985; O'Shea et al., 1985; Matson and Yovich, 1986), but Wardle et al. (1985) have shown that even mild endometriosis affects the quality of oocytes and reduces the fertilization rate. In our model of mild endometriosis the fertilization rates of rabbits in the experimental group were not different from those in the control group. This is in agreement with the findings of Hahn et al. (1986). From their and our study it can be concluded that the reduced fecundity, at least in rabbits with endometrial implants, is due to post-fertilization problems.

Tubal transport of the preimplantation embryo may be hampered in patients with mild endometriosis. Transport of ova through the Fallopian tube is effected by both muscular contractions and ciliary activity. Ovarian steroids, adrenergetic innervation and prostaglandins (PG) interact to influence oviductal contractility. In the rabbit, PGF$_2\alpha$, accelerates tubal transport of fertilized ova and subsequently reduces the implantation rate (Chang and Hunt, 1972; Salomy and Goldstein, 1978). In women, PGF$_2\alpha$ in pharmacological doses has a stimulatory effect on the contractility of the muscle layer of the Fallopian tube (Coutinho and Maia, 1971), but subsequent alteration of ovum transport could not be demonstrated (Croxatto et al., 1978). The role of endogenous PG in the spontaneous motility of the human Fallopian tubes is controversial (Elder et al., 1977). Moreover, peritoneal fluid PG concentrations in endometriosis are reported to be unchanged by some (Sgarlata et al., 1983; Rock et al., 1986), and increased by others (Drake et al., 1981; Ylikorkala et al., 1984). Therefore a causal relationship between peritoneal fluid PG and altered tubal transport, resulting in impaired fertility in endometriosis, is as yet unproven. The conflicting results obtained in measuring peritoneal fluid PG can be partly explained by methodological problems (Rock et al., 1986). However, the existence of two types of endometriosis, i.e. intra- and retroperitoneal, as described by Vasquez et al. (1984) might also be responsible for the differences found. Schenken and Asch (1980) found increased levels of peritoneal fluid PGF in rabbits with surgically induced endometriosis. They suggested that the increased levels of PGF could alter ovum transport. In a subsequent study, however, Schenken and Walters (1986) did not find a difference in tubal transport of fertilized ova in rabbits with endometriosis compared to controls. The results of our study are in agreement with the data.
reported by Schenkken and Walters (1986): at 24 h after mating, i.e. 12 h after ovulation, over 95% of fertilized ova were retrieved from the ampullary-isthmic junction on both sides in all animals studied (Table 8.1). Comparison of these data with figures reported in the literature (Land et al., 1987) reveal no marked differences with normal tubal transport in the rabbit. The results obtained indicate that in the rabbit endometrial implants without periadnexal adhesions, have no influence on tubal transport of fertilized ova during the first 24 h after mating. Our results, obtained with rabbits with mild endometriosis, have to be interpreted with some caution in trying to explain endometriosis-associated subfertility in the human. The endometrial implants in the rabbit, although histologically consistent with endometriosis, are not necessarily identical with endometriosis. Taking these restrictions into account, it is suggested that, since no differences were found in ovulation, ovum pickup, fertilization and tubal transport in the rabbit with endometrial implants, the decreased fecundity found with mild endometriosis in the human may be attributed to other, not implant-related, properties of this enigmatic disease, or may be caused by post-fertilization problems, e.g. disturbances in early embryonic development or implantation.

Chapter 9

Effect of endometriosis on early embryonic development in the rabbit

(Human Reproduction, accepted for publication)

Summary

The reasons for subfertility in patients with mild endometriosis remain unclear. Peritoneal fluid constituents may alter tubal transport and embryonic cleavage, with subsequent implantation disturbances. We used an animal model to study the influence of endometrial implants on early embryonic development. In 25 rabbits endometrium from the right uterine horn was transplanted onto the peritoneum (Experimental Group = Group E). In 25 rabbits fat was transplanted (Control Group = Group C). After a recovery period of 12 weeks the does were mated, and sacrificed 24 h later. In the experimental group the implants had changed into cysts of 5 to 15 mm in diameter. Histological examination revealed endometrial glands and stroma in every specimen. Periadnexal adhesions did not develop in any animal. No marked differences were found between Groups E and C in embryonic cleavage stage, 24 h after mating. Additional culturing of the embryos for 48 h in a suitable culture medium, revealed normal further development of the embryos. Bearing in mind the restrictions of a rabbit model, extrapolating to the human, it is suggested that the decreased fecundity in mild endometriosis is not caused by altered early embryonic cleavage rate. This offers indirect evidence for implantation disturbances as a cause of endometriosis-associated subfertility.
Introduction

If ovaries and tubes are encapsulated in adhesions, as can be the case in severe forms of endometriosis, ovulation, ovum pickup, fertilization and tubal transport are likely to be impeded. Impaired fertility in mild endometriosis, however, is difficult to explain. Changes in peritoneal fluid and its constituents might influence tubal transport and embryonic cleavage. Prostaglandins produced by peritoneal macrophages and endometriotic tissue are considered to play a role in the subfertility associated with endometriosis (De Leon et al., 1986) by altering ovum transport and possibly by interfering with implantation. Altered tubal transport of the fertilized ovum can lead to an untimely arrival of the fertilized ovum in the uterine cavity with subsequent implantation disorders. Considering synchronization of embryonic development with maternal environment at implantation, the cleavage rate of the developing embryo may be a critical factor as well.

In this paper we report on embryonic development of fertilized ova in the first 24 h after mating in an animal model of mild endometriosis. To study the possibly detrimental effects of the contact in the periovulatory phase between gametes, embryos and the altered peritoneal environment upon embryonic development, the embryos were further cultured in vitro in a suitable culture medium for an additional 24 h.

Materials and Methods

Virgin Dutch belted rabbits were used. The 50 does were caged individually at 20°C with a photoperiod of 12 h light: 12 h dark. They were fed 150 grams of rabbit chow daily and allowed water ad libitum. Before surgery each doe received 125 mg of ampicillin prophylactically by intravenous injection. Anaesthesia was induced with 0.2 mg atropine/kg and 0.5 ml Hypnorm/kg (10 mg fluanizone and 0.2 mg phentany per ml, Duphar, Amsterdam) intramuscularly. As soon as anaesthesia was achieved, each doe was intubated with an endotracheal tube. A mixture of halothane (0.5-1.0%), oxygen (1 litre/min) and nitrous oxide (2 litre/min) was given through a closed loop inhalation anaesthesia system (infant ventilator, MK2, Keuskamp, Amsterdam).

In all 50 rabbits a 1-cm segment of the right uterine horn as well as adipose tissue from the juxta-uterine fat was resected. After resection, the uterine horn was reaplastosed and the defect in the fat tissue closed by microsurgical methods. In 25 rabbits (Group E) the resected uterine horn was opened longitudinally and divided into four equal parts. These pieces of uterine tissue (consisting of endometrium, muscularis and serosa) were sutured onto the peritoneum at the right lateral abdominal wall, adjacent to uterus and ovary, with the serosal side of the uterine tissue fac-
ing the peritoneum, and the endometrium facing the peritoneal cavity, using 6.0
Prolene (Ethicon, Somerville, NJ, USA). In 25 rabbits (Group C) the fat was
divided into four equal parts and sutured onto the peritoneum in a comparable way.
In Group E the fat tissue was discarded and in Group C the uterine tissue was dis-
carded. The abdominal wall was closed in two layers with evertting interrupted su-
tures. After a recovery period of 12 weeks the does were mated with a buck of
proven fertility. To ensure and synchronize ovulation the does were given 125 IU
of human chorionic gonadotropin (Pregnyl: Organon, Oss, The Netherlands). The
does were killed 24 h after mating, i.e. 12 h after ovulation (Harper, 1961).
Anaesthesia was induced with 0.5 mg xylazine/kg (Rompun: Bayer, Leverkusen,
West Germany) and 0.4 ml ketamine/kg (Ketaset: Bristol Laboratories, New York)
by intramuscular injection. An overdose of pentobarbitone sodium was ad-
ministered intravenously and laparotomy was performed.
The abdominal cavity was carefully inspected for adhesions. The implants were ex-
cised for histological examination. The patency of the right reanastomosed uterine
horn was tested. The ovariies and Fallopian tubes were excised. The ovaries were ex-
amined under a stereomicroscope (Wild M8) to count the number of corpora lutea
in each ovary. The oviducts were divided into three parts representing the ampullary
segment, the ampullary-isthmus junction and the isthmic segment. The three seg-
ments of both oviducts were flushed with 5 ml of HEPES-buffered Whittingham’s
T6 culture medium adjusted to pH 7.4 (Quinn et al., 1984). The flushings were
checked for the presence of ova and embryos under a stereomicroscope (Wild M8).
The number of ova and embryos recovered from each oviduct was related to the
number of corpora lutea in the ovary at the same side in order to calculate the recovery
rate. The number of fertilized ova, the cleavage stage of each embryo and the
segment from which it was retrieved were recorded. From these data the embryonic
development 24 h after mating was determined for each tube separately. Criteria for
fertilization were the presence of sperm in the perivitelline space, the presence of two
polar bodies, the presence of two pronuclei or cleavage (Land, 1985). Thereafter the
embryos were transported to bicarbonate buffered Whittingham’s T6 culture medi-
um (Quinn et al., 1984) supplemented with 5 mg Bovine Serum Albumin (BSA) per
ml and incubated at 37°C in a humidified atmosphere containing 5% CO₂. After
48 h, (72 h after mating), the embryonic cleavage stage was determined.
The results obtained were compared between the right and left oviducts in each
group, and between the right oviducts and the left oviducts for Groups E and C.
Statistical analysis was performed using the Wilcoxon rank sum test for paired sam-
pies comparing right and left sides. The Wilcoxon rank sum test for unpaired sam-
plies was used to compare Groups E and C.

Results

In all rabbits of Group E the endometrial implants appeared to have developed in cysts consistent with endometriosis. Histological examination revealed endometrial glands and stroma in every specimen. In Group C the fat tissue had not changed since the operation and no endometrial tissue had developed.

In both Groups E and C the ovaries and oviducts were completely free of adhesions. The operated uterine horn was patent in all animals. The results of the parameters investigated are shown in Tables 9.1 and 9.2. The recovery rates did not differ significantly when the results obtained from the right sides of the animals were compared to those of the untouched left sides, for rabbits in Groups E and C. In the flushings of 4 oviducts no fertilized ova were found. Comparing the right to the
left side in Groups E and C revealed no marked differences in embryonic development 24 h after mating. Comparison of the right and the left side respectively between Group E and C showed no differences either. The embryos of 2 rabbits in Group C were not transferred to the culture medium. The percentage of embryos that reached the morula stage after 48 h culture, i.e. 72 h after mating, did not differ between the groups investigated (Table 9.2).

Discussion

Data obtained from studies on reduced fecundity in mild endometriosis in the human (Muse and Wilson, 1982) and in the experimental animal model for endometriosis (Vernon and Wilson, 1985) suggest that endometriotic implants may exert their unfavourable effects during the early stages of pregnancy. Apart from disturbances in ovulation, fertilization and tubal transport, the development of the preimplantation embryo may be hampered.

After fertilization embryonic cleavage takes place in the Fallopian tube. The influence of endometriosis on embryonic cleavage during tubal transport is unknown. Theoretically a decreased as well as an increased rate of cleavage can influence implantation by creating asynchrony between the developing embryo and the uterine environment. Changes in the composition of peritoneal fluid may influence embryonic cleavage. Gametes are under the influence of the peritoneal milieu for a short period in the periovulatory phase of the cycle. In endometriosis patients this hostile milieu might affect subsequent embryonic development and implantation. After culturing two-cell mouse embryos in medium supplemented with 5% peritoneal fluid of endometriosis patients for 24, 48 and 72 h, less advanced cleavage stages have been found as compared to cleavage stages of embryos cultured in medium supplemented with 5% peritoneal fluid of controls (Morcos et al., 1985).

The pregnancy rate in IVF has been reported to be the same in patients with mild endometriosis as compared to patients with occluded tubes (Chililk et al., 1985; Matson and Yovich, 1986). This might be explained by the fact that neither the oocyte, recovered from the preovulatory follicle, nor the spermatocytes come into direct contact with the hostile peritoneal milieu. After fertilization the process of early embryonic development takes place in the, perhaps more favourable, culture medium. However, good results have been obtained in infertile patients with mild endometriosis treated with gamete intrafallopian transfer (Asch, personal communication), when shortly after oocyte recovery the gametes were placed in the Fallopian tube. These favourable results might be due to the fact that the gametes have been exposed to the peritoneal milieu for a considerably shorter time period than during the normal process of ovulation and ovum pickup.

In our study, the percentage of two-cell embryos retrieved from the oviduct 24 h
after mating, did not markedly differ between Groups E and C. Comparing the right and the left sides respectively between Groups E and C revealed no differences either. These figures are comparable with those found in the literature (Land, 1985). Culturing embryos in peritoneal fluid for more than 24 h, however, seems to be an unrealistic procedure. Taking into account the fluid currents in the Fallopian tube we hypothesized that tubal fluid in endometriosis patients is not different from controls, and that possible changes in peritoneal fluid composition do not affect tubal fluid composition. Therefore we decided to culture the embryos further, after the initial 24 h, in a balanced salt solution, Whittingham's T6. The percentage of fertilized ova and embryos that reached the morula stage after culture in this medium for 48 h was not different among the groups investigated.

Changes in folliculogenesis and oocyte maturation caused by the presence of peritoneal and ovarian endometriosis might, however, without decreasing the oocyte's fertilizability, influence embryonic cleavage to an extent not yet discernible 24 or 72 h after mating. In our study in rabbits with endometrial implants no differences were found regarding embryonic cleavage rate in the periods investigated. But as time elapses slight alterations, not yet apparent soon after fertilization, may become more pronounced and cause asynchrony at implantation. The design of our study did not allow to examine implantation, since the embryos were flushed from the oviducts 24 h after mating. In the rat the presence of ectopic endometrial tissue significantly reduced the number of day 14 embryos (Vernon and Wilson, 1985). A comparable reduction, due to a failure of implantation or to early spontaneous abortion secondary to the presence of endometrial implants, was found by Hahn et al. (1986) in the rabbit.

In conclusion, results obtained in an experimental model of mild endometriosis indicate that endometrial implants in the rabbit do not influence the embryonic cleavage rate during the first 24 h in vivo, nor during the next 48 h in an artificial tubal environment.

Interpreting results, obtained in an experimental rabbit model of endometriosis, to explain causes of subfertility in human endometriosis remains precarious. Endometrial implants in the rabbit histologically mimic, but do not necessarily have to be identical to human endometriosis. Moreover, rabbits are reflexovulators and lack menstrual cyclicity. Consequently no cyclic changes occur in the ectopic, implanted, endometrium.

Bearing in mind these restrictions, and provided that the endometrial implants in the rabbit constitute a valid model of endometriosis in the human, the results of the present investigation suggest endometriosis-associated subfertility not to be caused by alterations in early embryonic development. Our previous study in the same rabbit-model of endometriosis (Dunselman et al., 1988) did not show differences in ovulation, ovum pickup, fertilization and tubal transport. Therefore, either early embryonic effects only will become manifest during later stages of development or subsequent embryonic development and/or implantation will be affected directly by endometriosis.

Chapter 10

General discussion

Endometriosis is often, but not exclusively, found in infertile patients. Although epidemiological and clinical data suggest a cause and effect relationship, it has not been demonstrated conclusively that endometriosis does produce infertility. A third, as yet unknown, mechanism might be responsible for both endometriosis and infertility. If, however, endometriosis does cause infertility, this is most likely effectuated by an alteration of the intraabdominal milieu, the microenvironment in which reproductive processes take place. We assumed that these changes in the intraabdominal milieu would be reflected in the peritoneal fluid composition. Results from the first part of this thesis lend support to the theory that certain intraabdominal changes occur in patients with macroscopically visible endometriosis, i.e. numbers and concentrations of peritoneal cells increase and advanced stages of differentiation of peritoneal macrophages develop. Other possible indices of changes in the intraabdominal environment, peritoneal fluid volume and concentrations of peritoneal fluid acute-phase proteins, appeared not to be affected or only to a minor degree by the presence of endometriosis.

It has been suggested that non-visible, microscopic, endometriosis may account in part for what usually is referred to as unexplained infertility. Therefore, we compared the results of the parameters determined for three subgroups of patients, i.e. infertile patients with endometriosis, infertile patients without endometriosis, and fertile controls without endometriosis in addition to the comparisons as described in the chapters 4, 5 and 6. Because of the cyclic variation in peritoneal fluid volume and peritoneal fluid constituents, only patients in the postovulatory phase of the cycle were compared.

Peritoneal fluid volume in the postovulatory phase of the cycle was not significantly different between infertile patients with and without endometriosis. Peritoneal fluid volume of infertile patients, with and without endometriosis, was shown to be significantly higher than that of fertile patients without endometriosis.

Comparison of the concentrations of the individual proteins in serum and peritoneal fluid and the p/s ratios for these proteins between the three subgroups did not reveal a significant difference for any of the proteins measured. The same applied to the peritoneal fluid concentrations of the parameters of intraabdominal fibrinolysis. The total number and concentration of peritoneal cells, the erythrophagocytosis and the chemiluminescence of macrophages have also been compared between the subgroups. Total numbers and concentrations of peritoneal cells were comparable in infertile patients with and in infertile patients without endometriosis, but they were higher in infertile patients - with and without endometriosis - than in fertile controls.
without the disease. Peritoneal macrophages of infertile patients with endometriosis showed a significantly advanced level of differentiation, compared to both infertile patients without visible endometriosis and to fertile controls.

From these results it is concluded that it is not the presence of visible endometriosis but rather the fertility status of the patient that is related to the changes of the intraabdominal milieu as measured by peritoneal fluid volume, total numbers and concentrations of peritoneal cells. The advanced differentiation of the macrophages, however, seems to be predominantly related to the presence of visible endometriosis. It remains to be explained why increased peritoneal fluid volumes, increased numbers and concentrations of peritoneal cells were found in infertile patients with and without visible endometriosis, whereas an advanced stage of differentiation of macrophages was found only in the patient group with macroscopic endometriosis. What is recognized at laparoscopy as visible endometriosis represents the sequelae of repeated episodes of cyclic changes in the endometrial implants. In this stage of the disease not only quantitative changes occur in the inflammatory system: soluble mediators that are produced continuously by the implants attract monocytes from the peripheral blood. After their arrival in the peritoneal cavity the macrophages try to restore homeostasis, they support the proliferation of fibroblasts and the formation of scar tissue in an attempt to infiltrate, block off and delimit the areas of irritant activity. These are functions of macrophages in an advanced stage of differentiation. From the findings of this study it appears that quantitative changes, increased numbers of peritoneal cells, occur in both groups of patients with and without visible endometriosis, whereas qualitative changes, an advanced stage of differentiation of peritoneal macrophages, occur only when macroscopically visible endometriosis is present.

Peritoneal fluid concentrations of the different proteins determined were not related to the fertility status of the patient: comparable protein concentrations, mainly determined by their molecular weights, were found in all three subgroups investigated. The proteins involved in the fibrinolytic system appeared not to be affected by the presence of endometriosis, nor by the fertility status of the patient. Conceivably the fibrinolytic system constitutes a normal defense mechanism of the peritoneal cavity.

It is thus apparent that the intraabdominal milieu of patients with unexplained infertility shares characteristics with that of infertile patients with endometriosis. These observations may be explained in two different ways. In the first place, patients with unexplained infertility may harbor foci of non-visible endometriosis. The existence of microscopic endometriosis has been suggested by Acosta et al. (1973), while addressing the issue of surgical treatment of endometriosis. Microscopic endometriosis has been documented by Brosens et al. (1984) and Murphy et al. (1986). These foci of non-visible endometriosis may alter the intraabdominal environment of patients with unexplained infertility in a way comparable to macroscopic endometriosis. Vernon and coworkers (1986) suggested these microscopic lesions to be even more active than the older lesions which are recognizable to the naked eye. On the other hand, and possibly not mutually exclusive, a change in the intraab-
dodinal milieu and the presence of endometriosis may represent two pathologic entities governed by the same denominator. Retrograde menstruation may be the cause of both a chronic inflammatory state in the abdominal cavity and of the presence of endometriosis. Since retrograde menstruation is probably a common event (Blumenkrantz et al., 1981; Halme et al., 1984) the ability of endometrial cells to implant must be regulated by an as yet unknown mechanism. Implantation may be dependent on obstructed menstrual flow resulting in an increased amount of menstrual debris reaching the abdominal cavity and on the capacity of the individual patient to clear the abdominal cavity from this menstrual debris. Implantation or rejection of endometrial cells may be under the control of the cell-mediated immune system (Dmowski et al., 1981; Steele et al., 1984; Zeller et al., 1987). To date no tests are available to identify those women who are at risk to develop microscopic and/or macroscopic endometriosis nor to identify those women who will develop endometriosis related infertility.

Peritoneal macrophages of patients with endometriosis show an advanced stage of differentiation. These macrophages originate from the bone marrow. It is conceivable that peripheral monocytes are changed also. Indeed, Zeller et al. (1987), recently reported altered peripheral monocytes in patients with endometriosis. They suggested that endometriosis is a systemic rather than a local intraabdominal disease. These results have not yet been confirmed by others.

In conclusion, the changes in the intraabdominal environment are not related exclusively to the presence of visible endometriotic implants. The intraabdominal changes appear to be related to retrograde menstruation and/or to the secretory activity and shedding of the endometriotic lesions and the exudation of the peritoneal mesothelial lining. Qualitative changes of the macrophages appear to be a marker of macroscopic endometriotic lesions.

We did not study the impact of these changes on fertility. The literature on endometriosis-related infertility must be interpreted with caution. It is attractive to formulate a cause and effect relationship between two entities that are so often found to be coincidental. A third mechanism may be responsible for both endometriosis and infertility.

Changes in peritoneal fluid constituents found in patients with endometriosis are too easily linked to results of animal research or in vitro studies. The available literature on peritoneal fluid constituents in endometriosis patients does not correlate changes in these constituents with the subsequent occurrence of pregnancy, with the exception of a retrospective study by Syrop and Halme (1986) who showed that the occurrence of pregnancy was related to the volume of peritoneal fluid and not to the number of peritoneal cells. The higher the peritoneal fluid volume at the initial laparoscopy the lower the chances to get pregnant. Nevertheless, far reaching conclusions are invariably drawn regarding the negative influence of the findings on fertility. There are no reports in the literature on peritoneal fluid constituents before and after treatment of endometriosis, that relate the presence or absence of these constituents to the occurrence of pregnancy. The changes found in the intraabdomi-
nal milieu may well be epiphenomenal to the disease and, as discussed above, might represent a marker of retrograde menstruation as well. These findings will have a strong bearing on the treatment of endometriosis-associated infertility in the uncomplicated stage. In view of the above, it seems unrealistic to think that we can treat endometriosis-associated infertility by eliminating all visible endometriotic lesions at laparoscopy. On the other hand, elimination of macroscopic lesions might reduce the advanced differentiation of the peritoneal macrophages and allow, at least temporarily, a pregnancy to occur. Microscopic lesions remain however, and the disease will return with time.

If we accept that retrograde menstruation is the common denominator of both the presence of visible endometriosis and of the infertility seen in some patients with endometriosis (and possibly in patients with so-called unexplained infertility) a therapeutic approach may be formulated. The management of an infertile patient with newly diagnosed minimal or mild endometriosis can be conservative for a period of time, whether or not after coagulation or laser vaporization of all visible lesions at the initial laparoscopy. All possible efforts should be made to overcome those additional infertility factors, that are more commonly found in endometriosis patients, like inappropriate follicular development, luteal phase inadequacy and male subfertility. If this is not successful, it may be sufficient to stop retrograde menstruation for a period of time in order to 'clear' the abdominal cavity. The commonly used hormonal treatment combines amenorrhea with an effect on the endometrial implants. It is unclear which of the two is the most beneficial with regard to infertility. After two to four months of medical treatment for endometriosis, pregnancy should be pursued with all possible means, i.e. making use of ovulation detection and, if necessary, of ovulation induction. If this fails as well the next step may be in vitro fertilization, gamete intrafallopian transfer or intrauterine insemination. It has been shown that in patients with mild endometriosis and in patients with unexplained infertility intrauterine insemination combined with mild ovarian hyperstimulation results in a high number of pregnancies per cycle, exceeding the results of in vitro fertilization and embryo transfer or gamete intrafallopian transfer (Dodson et al., 1987). It remains to be investigated whether these results can also be achieved by either intrauterine insemination alone or by mild ovarian hyperstimulation alone. The latter approach has been shown to be effective in patients with long-standing idiopathic infertility (Welner et al., 1988).

It has been outlined before that it is difficult to study the influence of changes in the intraabdominal milieu secondary to endometriosis on fertility in the human. The different stages of early embryonic development cannot be investigated in detail. In vitro fertilization studies in endometriosis patients can solve these problems only incompletely.

An animal model of endometriosis may be a useful tool to study the different aspects, although, as has been outlined before, extrapolations between animal models and human conditions must be made with utmost care.
Theoretically, endometrial implants in the rabbit may change the intraabdominal environment in a way dissimilar to what occurs in human subjects. As discussed above, the changes in intraabdominal milieu in the human are related to both retrograde menstruation and to the endometrial implants per se. In the rabbit, a non-cycling animal, the abdominal cavity is not subjected to repeated episodes of retrograde menstruation. If changes occur in the intraabdominal milieu in the rabbit model of endometriosis then they are caused exclusively by the endometrial implants. Consequently, the rabbit model we used allows to study the influence of endometrial implants per se on fertility.

If endometrium implants cause a reduction of fertility in the rabbit, like it is presumed to do in the human, then this reduction takes place after the early embryonic period, as shown by the results of our study. It remains possible, however, that the effects of disturbances in early embryonic development become manifest only after a certain period of time, leading to problems at the time of implantation or in the early postimplantation period. The anti-implantation effect is supposed to be related to the presence of immunoglobulins and complement in the endometrium in patients with endometriosis (Weed and Arquembourg, 1980; Mathur et al., 1982; Bartosik et al., 1987). Early pregnancy loss may have accounted for the reduced fertility seen in a comparable rabbit model by other investigators (Hahn et al., 1986).

Peritoneal fluid research in patients with endometriosis performed to detect a possible cause and effect relationship between endometriosis and infertility and to study the etiology of endometriosis is hampered by several problems. In the first place, endometriosis still lacks a precise definition and classification. In the revised classification of the American Fertility Society (R-AFS)(1985) the group of minimal endometriosis invariably harbors a wide spectrum of macroscopically different lesions. All these lesions probably have their own biological potential and have a different impact on the composition of the peritoneal fluid. On top of this problem is the possible presence of microscopic endometriosis in fertile and infertile patients. Another problem in studying peritoneal fluid constituents is the complex regulation of peritoneal fluid volume, protein concentration and cell content. Absorption of the peritoneal fluid is by the venous side of the same subperitoneal capillaries that produce it. Proteins and cellular constituents are removed via the lymphvessels at the right side of the diaphragm (Review by Kroon, 1986). Insufficient data are available about the regulation of this in- and outflow across the peritoneum and about the turnover of proteins. Peritoneal fluid used for the study of the intraabdominal environment in which early embryonic development takes place should be collected at a moment of the cycle that is well defined in relation to the process of ovulation. If comparisons are to be made between patients with and without endometriosis care should be taken to accurately diagnose presence or absence of the disease. Familiarity with the early stages of minimal endometriosis is mandatory. Sufficient biopsies should be taken to exclude microscopic disease. To outline the influence of certain changes on ferti-
ty, the parameters studied should be related to the occurrence of pregnancy. But, most of all, the complex regulatory mechanisms of peritoneal fluid volume and its constituents should be studied in detail.

Novak's statement in 1931 about progress in understanding endometriosis is equally applicable today, and, perhaps even more so, to the study of peritoneal fluid in relation to endometriosis-associated infertility: "Investigators have apparently worked themselves into a scientific cul-de-sac from which they can be rescued only by discovery of some new method of attacking the problem".

Summary

Chapter 1 offers a short introduction in which a definition of endometriosis is given. In the first part of chapter 2 the literature is reviewed regarding pathogenesis and etiology, classification, epidemiology, symptomatology, diagnosis, management and recurrence. The second part of chapter 2 contains a review of the literature on the relationship between endometriosis and infertility and on the pathophysiological changes in the abdominal cavity as reflected in the peritoneal fluid that take place in patients with endometriosis. The third part of chapter 2 gives a review of the literature on the use of different animal models of endometriosis.

The aim of this thesis is outlined in chapter 3. In the first place changes in the intraabdominal milieu secondary to the presence of endometriosis were documented. Furthermore the influence of peritoneal implants of endometrium on early embryonic development was studied in the rabbit.

Chapter 4 and 5 describe changes in peritoneal fluid volume and its constituents in the presence of endometriosis. Peritoneal fluid was collected at laparoscopy performed in the course of an infertility workup (N = 40), for abdominal pain (N = 9) and for sterilization (N = 21). In chapter 4 it is shown that there is no difference in peritoneal fluid volume and in peritoneal fluid/serum ratios of acute phase proteins between 25 women with and 45 women without endometriosis. The concentration of the individual proteins in the peritoneal fluid is shown to be predominantly dependent on their molecular weight in both groups. It is concluded that endometriosis does not cause marked intraabdominal inflammatory changes, as far as these might be reflected in changes in intraabdominal protein concentrations.

In chapter 5 parameters of fibrinolysis measured in peritoneal fluid are compared between 25 women with endometriosis and 45 women without the disease. No differences were found between the two groups. It is concluded that changes of the fibrinolytic system do not play a role in endometriosis. In all patients a high concentration of tissue plasminogen activator in peritoneal fluid in comparison to normal blood levels was found, leading to a high concentration of fibrin degradation products in peritoneal fluid. This indicates an active system of intraabdominal fibrinolysis, irrespective of the presence of endometriosis and thus possibly reflecting a normal intraabdominal defense mechanism.

In chapter 6 functional aspects of peritoneal macrophages are studied in 13 women with and 12 women without endometriosis. In women with endometriosis the total number and the concentration of peritoneal cells were significantly higher than in controls, indicating peritoneal irritation by endometrial implants. Peritoneal fluid
macrophages of women with endometriosis showed significantly increased erythrophagocytosis and lower chemiluminescence. This suggests an advanced stage of differentiation of these macrophages. Macrophages in this stage of differentiation possibly interfere with gametes and embryos and thus contribute to endometriosis-associated subfertility.

Chapters 7, 8 and 9 are devoted to experimental aspects. In chapter 7 the rabbit model of endometriosis that was used to study the influence of endometrial implants on fertility is described. Twelve weeks after implantation of endometrial tissue into the peritoneal cavity of rabbits cystic structures were found in place of the implants. These cysts were macroscopically and histologically consistent with endometriosis. Moreover, no periadnexal adhesions developed. It is concluded that the rabbit model is suitable to study the influence of endometrial implants on fertility.

In chapter 8 and 9 results obtained in the above mentioned experimental model are described. In 25 rabbits with endometrial implants and in 25 rabbits with fat implants the number of corpora lutea, the recovery rate, the fertilization rate and the transport of fertilized ova 24 hours after mating were determined. No differences were found between the two groups, as shown in chapter 8. From the results obtained it is concluded that endometriai implants in the rabbit have no influence on the ovulatory mechanism, the pickup function of the oviduct, the fertilization rate or on the transport of fertilized ova.

In chapter 9 the influence of endometrial implants versus the influence of fat implants on the embryonic cleavage stage 24 h after mating is described. No differences were found between the two groups. Additional culturing of the embryos for 48 hours in a suitable culture medium revealed a further development of the embryos, that did not differ between the two groups studied.

Taking into account the restrictions of a rabbit model of endometriosis it is suggested that the decreased fecundity in mild endometriosis in the human may be caused by disturbances that take place after the early embryonic period. It remains possible that the effects of disturbances in early embryonic development become manifest only after a certain period of time, leading to problems at the time of implantation or in the early postimplantation period.

In chapter 10 an attempt is made to integrate the previous chapters with the existing literature. The possibility that patients with unexplained infertility harbor microscopic foci of endometriosis is supported by findings of the present investigation. The intraabdominal changes detected are not related exclusively to the presence of visible endometriotic implants.

It is emphasized that a cause and effect relationship between endometriosis and infertility cannot be concluded from the available literature. A third mechanism may be responsible for both endometriosis and infertility. Likewise, most reports on peritoneal fluid constituents in endometriosis do not correlate changes in these constituents with the subsequent occurrence of pregnancy. The consequences of these observations with regard to the treatment of endometriosis are shortly discussed.
Samenvatting

Hoofdstuk 1 bestaat uit een korte inleiding, waarin het ziektebeeld endometriosis wordt gedefinieerd.

In het eerste gedeelte van hoofdstuk 2 wordt een overzicht gegeven van de literatuur betreffende pathogenese en etiologie, classificatie, symptomatologie, diagnose, behandeling en recurrence. Het tweede gedeelte bespreekt de literatuur betreffende het verband tussen endometriosis en infertilité en betreffende de pathofysiologische veranderingen die optreden in de buikholte in de aanwezigheid van endometriosis, zoals weerspiegeld in de peritoneumvloeistof. Het derde gedeelte van hoofdstuk 2 bevat een overzicht van de literatuur betreffende het gebruik van verschillende dierexperimentele modellen van endometriosis.

Het doel van het onderzoek beschreven in dit proefschrift wordt uiteengezet in hoofdstuk 3: het in kaart brengen van de veranderingen die plaatsvinden in het intra-abdominale milieu ten gevolge van de aanwezigheid van endometriosis, en het bestuderen van de invloed van endometrium implantaten op de vroegeembryonale ontwikkeling in een konijnemodel van endometriosis.

In hoofdstuk 5 worden parameters van de fibrinolysis, gemeten in de peritoneumvloeistof, vergeleken tussen 25 vrouwen met en 45 vrouwen zonder endometriosis. Er werden geen verschillen aangetoond tussen de twee groepen. Hieruit wordt geconcludeerd dat het fibrinolytische systeem geen rol speelt bij endometriosis. Bij alle patiënten werd een hoge concentratie tissue plasminogen activator in de peritoneumvloeistof gevonden in vergelijking met de waarden die normaal in het perifere bloed worden aangetroffen. Dit had een hoge concentratie fibrine-afbraakproducten in de peritoneumvloeistof tot gevolg. Deze bevindingen wijzen op een actief systeem van intra-abdominale fibrinolysis. Echter dit was onafhankelijk van de aanwezigheid
van endometriosis. Deze actieve fibrinolysis kan beschouwd worden als een fysiologisch intra- abdominaal afweermecanisme.

In hoofdstuk 6 worden functionele aspecten van peritoneale macrofagen bestudeerd bij 13 vrouwen met en 12 vrouwen zonder endometriosis. Bij vrouwen met endometriosis waren het totale aantal en de concentratie van intra-abdominale cellen signifi- cant hoger dan bij de controlegroep, wat mogelijk wijst op irritatie van het peritoneum door endometriosis.

De macrofagen in de peritoneumvloeistof van vrouwen met endometriosis vertoonen een significant verhoogde erythrofagocytosis en een significant verlaagd chemi- luminescentie. Dit is een aanwijzing voor een gevorderd stadium van differentiatie van deze macrofagen.

Macrofagen in dit stadium van differentiatie kunnen interfereren met gameten en embryo’s om bij te dragen aan de vermindere vruchtbaarheid die gezien wordt bij vrouwen met endometriosis.

De hoofdstukken 7, 8 en 9 zijn gewijd aan experimentele aspecten.

In hoofdstuk 7 wordt het konijnennmodel van endometriosis beschreven dat werd ge- bruikt om de invloed van endometriumimplantaten op de fertilité te bestuderen. Twaalf weken na implantatie van endometriumweefsel in de buikholte van konijnen werden cystes aangetroffen op de plaats van de implantaten. Deze cystes vertoonden macroscopisch en histologisch overeenkomst met endometriosis. Bovendien ont- stonden geen adhesies rond tubae en ovaria. De conclusie luidt dat het konijnennmodel een geschikt model is om de invloed van endometriumimplantaten op de fertilité te bestuderen.

In hoofdstuk 8 en 9 worden de resultaten beschreven verkregen met behulp van het hierboven genoemde model. Bij 25 konijnen met endometriumimplantaten en bij 25 konijnen met vetimplantaten werden de volgende parameters bepaald: het aantal corpora lutea, het aantal embryo’s teruggevonden bij spoelen van de tubae, het be- vruchtingspercentage en het transport van de bevruchte eicellen 24 uur na dekkien van het konijn. Er werden geen verschillen gevonden tussen de twee groepen. Hier- uit wordt geconcludeerd dat endometriumimplantaten bij het konijn geen invloed hebben op het ovulatiemechanisme, de opvang van de eicel, het aantal eicellen dat bevrucht wordt en op de snelheid van transport van de bevruchte eicellen door de eileiders.

In hoofdstuk 9 wordt de invloed van endometriumimplantaten beschreven versus de invloed van vetimplantaten op het delingsstadium van de embryo’s gedurende de eerste 24 uur na dekken van het konijn. Er werden geen verschillen gevonden tussen de twee groepen. Vervolgens werden de embryo’s doorgekweekt in een geschikt kweekmedium gedurende 48 uur. Ook hierbij werden geen verschillen tussen de twee groepen aangetoond.

De beperkingen van een konijnennmodel van endometriosis in aanmerking genomen kan men veronderstellen dat de vermindere vruchtbaarheid bij endometriosis ver-oorzaakt wordt door stoornissen die optreden na de vroegembryonale periode. Het blijft mogelijk dat de effecten van stoornissen in de vroegembryonale periode pas
tot uiting komen na enige tijd, aanleiding gevend tot problemen ten tijde van de implantatie of in de periode direct volgend op de implantatie.

In hoofdstuk 10 wordt gepoogd de inhoud van de voorgaande hoofdstukken in de context te plaatsen van de bestaande literatuur. De mogelijkheid dat patienten met onbegrepen infertiliteit microscopische endometriosis hebben wordt ondersteund door de bevindingen van het hier beschreven onderzoek. De aangetoonde intra-abdominale veranderingen zijn niet uitsluitend gekoppeld aan de aanwezigheid van macroscopische endometriosis.

Benadrukt wordt dat een oorzakelijk verband tussen endometriosis en infertiliteit niet volgt uit de beschikbare literatuur. Een derde mechanisme kan verantwoordelijk zijn voor zowel de endometriosis als de infertiliteit. Een tekortkoming van de geraadpleegde literatuur bleek te zijn dat veranderingen in peritoneumvloeistofsaamstelling bij patienten met endometriosis niet worden gecorreleerd aan het optreden van zwangerschappen. De consequenties van deze bevindingen voor de behandeling van endometriosis worden besproken.
