Lack of PIVKA Effect in the Abnormal Factor X (Factor X Friuli) Coagulation Disorder

A. GIROLAMI, A. D. MULLER and H. C. HEMKER

Laboratories of Cardiovascular Biochemistry and Blood Coagulation Biochemistry,
University Hospital, Leiden

Abstract. Thrombotest dilution curves and specific inhibitor experiments were carried out in the abnormal factor X (factor X Friuli) plasma and in coumarin plasma. Thrombotest dilution curves obtained with Friuli plasma suggested the presence of a PIVKA-like inhibitor which was not confirmed by the specific experiments. The inhibitory capacity found in Friuli plasma was -0.09 arbitrary units, whereas that found in coumarin-treated patients with a factor X level ranging from 1 to 14% varied between 0.34 and 0.21 arbitrary units.

Key Words

Factor X Friuli
PIVKA effect
Coumarin-induced inhibition
Thrombotest

The occurrence of a blood coagulation inhibiting protein in the plasma of patients treated with anticoagulants was first suspected on the observation that the levels of factors II, VII and X as determined in specific assays did not correspond to those obtained in the thrombotest system [12, 15]. This hypothesis was confirmed later on the basis of kinetic experiments. The action of this protein can be explained by admitting it to act as an analogue of normal coagulation factors [14]. It was postulated that the inhibitor consists of precursors which cannot be converted into the normal factors because a final vitamin K-dependent step in their synthesis is blocked. The existence of such proteins induced by vitamin K absence (PIVKAs) was demonstrated recently by immunological methods [18-20].

The abnormal factor X (factor X Friuli) coagulation disorder was first described in 1969 and 1970 [4, 5]. This abnormal factor X cannot be activated or it can be activated only very slowly by partial or whole tissue thromboplastin, whereas it can still be normally activated by Russell's viper venom

Received: November 21, 1972; accepted: November 27, 1972.

(RVV). As a consequence factor X results to be low only when assayed using whole or partial tissue thromboplastin; if factor X is assayed according to the method of BACHMANN *et al.* [1] and DENSON [2] it results to be normal or near normal.

The name 'Friuli' was attached to the conditions since all the patients originally described to have this disorder came from an isolated valley in the northeastern Italian region called 'Friuli' [5, 6]. On theoretical grounds, it could be speculated that this congenitally determined abnormality could have some similarities with the coumarin-induced abnormal form.

These considerations and the observation of an inhibitory type of thrombotest dilution curve for the Friuli plasma prompted this report.

Material and Methods

Friuli plasma was obtained in Padova from one of the patients known to have this disorder (patient M.P.) [5]. The platelet-free citrated plasma was stored in plastic tubes at -20°C in 5 ml aliquots and brought to Leiden frozen. In these studies we used plasma samples drawn on four different dates (16.11.1971, 14.12.1971, 4.2.1972 and 12.10.1972).

The factor X content in the frozen Friuli plasma as determined in Leiden with human brain thromboplastin was 6.8 % of normal. This was in good agreement with the results obtained in Padova for the same patient on fresh plasma [5, 8]. The mean factor II, factor V and factor VII levels in frozen Friuli plasma samples were 64.4, 132.2 and 77.8 %, respectively, in good agreement with the values obtained in Padova on fresh plasma [5], and within the limits found in plasma from normal persons.

Platelet-free citrated normal plasma was obtained from 30 healthy persons, aged about 30 years, and stored in plastic tubes at -20°C in 10 ml aliquots.

Platelet-free plasma of an overanticoagulated patient (attempted suicide). The factor X content in this plasma was about 1 % of normal, whereas its factor II, V and VII content was 1, 64 and 1 %, respectively [14].

Human brain thromboplastin, batch 1926 Leiden, was prepared according to a modification of the method of OWREN and AAS [17]. Factor X reagent was prepared as previously reported [16]. The batch used (batch No. 1110) contained 0.98 % factor X.

'*Fake*' *Friuli plasma* was prepared by mixing 6 parts of normal plasma with 94 parts of factor X reagent. The factor X content was 11.0 %, whereas factors II, V, and VII were 22.8, 60.6 and 41.6 %, respectively.

'*Fake*' *coumarin plasma* was prepared by mixing 99 parts of $\text{Al}(\text{OH})_3$ adsorbed normal plasma with 1 part of normal plasma. The factor II, VII, and X content of this 'fake' plasma was 1 % of normal.

Thrombotest dilution tests were carried out with 1:1, 1:2, 1:3, 1:5 and 1:10 Michaelis buffer diluted Friuli plasma, coumarin plasma and normal plasma. Thrombotest reagent was supplied by Nyegaard Laboratories, Oslo (Batch 123). The investigation of specific inhibition by Friuli plasma was carried out as previously reported [14]. Normal plasma

was diluted 1:1, 1:2, 1:3, 1:4, 1:5, 1:6, 1:7, 1:8, 1:9, and 1:10 in factor X reagent. These dilutions were kept in plastic tubes at 0 °C. Then to a 0.075-ml aliquot of each of such dilutions 0.025 ml Friuli plasma or 'fake' Friuli plasma were added. In the case of coumarin plasma or 'fake' coumarin plasma, the volumes were 0.05 ml each. Eventually factor X was assayed in all mixtures by means of a one-stage method using human brain thromboplastin. Clotting times were then plotted against the inverse of factor X concentration. In such a curve a competitive inhibitor causes the straight line giving t_c as a function of $1/(\times)$ to become steeper, maintaining the same interaction with the ordinate. Thus, the same t_{min} is read as with the inhibitor present, but a different K_m is found.

The inhibitory capacity of the plasma tested can be assessed from the curves obtained by calculating the ratio K'_m/K_m , K_m being the Michaelis constant of the uninhibited series and K'_m the apparent K_m of the inhibited series.

$$\text{As } K'_m = K_m \left(1 + \frac{i}{k_i}\right) \quad I = -\frac{i}{k_i} = \frac{K'_m}{K_m} - 1, \quad k_i \text{ being the unknown constant.}$$

This is the closest we can get to quantitate c_i , i.e. the concentration of the inhibitor.

Results

The results of thrombotest dilution studies are reported in figure 1. The Friuli plasma dilution curve as well as the coumarin plasma dilution curve obtained with the (aspecific) thrombotest reagent do not meet the Y-axis at the same point as the normal plasma dilution curve does. This would seem to indicate the presence of an inhibitor and prompted us to try and find inhibition in specific experiments where only the concentration of factor X is varied. Such inhibition can be demonstrated to occur in coumarin plasma [14].

The specific experiments are summarized in table I and II, and in figures 2 and 3. No inhibitory effect seems present in Friuli plasma since the clotting times obtained at equivalent factor X concentrations are practically identical to those obtained for the 'fake' Friuli plasma (inhibitory capacity: $I = -0.09$). On the contrary, in the case of the overanticoagulated plasma, a clear inhibitory effect was present. At equivalent factor X concentrations the clotting times were longer than those obtained for the 'fake' coumarin plasma. These data are in agreement with the results obtained in other patients given coumarin-like drugs for therapeutic purposes. In a series of coumarin plasmas the inhibitory capacity I varied between 0.39 and 0.29 without any apparent correlation with the concentration of factor X (which varied between 1 and 14 %).

was diluted 1:1, 1:2, 1:3, 1:4, 1:5, 1:6, 1:7, 1:8, 1:9, and 1:10 in factor X reagent. These dilutions were kept in plastic tubes at 0 °C. Then to a 0.075-ml aliquot of each of such dilutions 0.025 ml Friuli plasma or 'fake' Friuli plasma were added. In the case of coumarin plasma or 'fake' coumarin plasma, the volumes were 0.05 ml each. Eventually factor X was assayed in all mixtures by means of a one-stage method using human brain thromboplastin. Clotting times were then plotted against the inverse of factor X concentration. In such a curve a competitive inhibitor causes the straight line giving t_c as a function of $1/(\times)$ to become steeper, maintaining the same interaction with the ordinate. Thus, the same t_{min} is read as with the inhibitor present, but a different K_m is found.

The inhibitory capacity of the plasma tested can be assessed from the curves obtained by calculating the ratio K'_m/K_m , K_m being the Michaelis constant of the uninhibited series and K'_m the apparent K_m of the inhibited series.

$$\text{As } K'_m = K_m \left(1 + \frac{i}{k_i}\right) \quad I = \frac{i}{k_i} = \frac{K'_m}{K_m} - 1, \quad k_i \text{ being the unknown constant.}$$

This is the closest we can get to quantitate c_i , i.e. the concentration of the inhibitor.

Results

The results of thrombotest dilution studies are reported in figure 1. The Friuli plasma dilution curve as well as the coumarin plasma dilution curve obtained with the (aspecific) thrombotest reagent do not meet the Y-axis at the same point as the normal plasma dilution curve does. This would seem to indicate the presence of an inhibitor and prompted us to try and find inhibition in specific experiments where only the concentration of factor X is varied. Such inhibition can be demonstrated to occur in coumarin plasma [14].

The specific experiments are summarized in table I and II, and in figures 2 and 3. No inhibitory effect seems present in Friuli plasma since the clotting times obtained at equivalent factor X concentrations are practically identical to those obtained for the 'fake' Friuli plasma (inhibitory capacity: $I = -0.09$). On the contrary, in the case of the overanticoagulated plasma, a clear inhibitory effect was present. At equivalent factor X concentrations the clotting times were longer than those obtained for the 'fake' coumarin plasma. These data are in agreement with the results obtained in other patients given coumarin-like drugs for therapeutic purposes. In a series of coumarin plasmas the inhibitory capacity I varied between 0.39 and 0.29 without any apparent correlation with the concentration of factor X (which varied between 1 and 14 %).

Fig. 1. Thrombotest dilution curve with normal plasma, Friuli plasma and coumarin-treated plasma. The extrapolations of the Friuli plasma and coumarin plasma curves to the Y-axis do not meet with the extrapolation of the normal curve. The coumarin plasma used in this experiment had a factor X content of 14 %, whereas factor II, V and VII were 21, 100 and 22 %, respectively. Using the overanticoagulated plasma, no curve could be constructed because of the extremely prolonged or infinite clotting times obtained.

Fig. 2. Lack of PIVKA effect in Friuli plasma. No difference is evident between Friuli plasma (O) and 'fake' Friuli plasma (●). Inhibitory capacity $I = -0.09$.

Fig. 3. Behaviour of the overanticoagulated plasma in the specific PIVKA experiment. At comparable factor X concentrations clotting times are longer in coumarin plasma (O) as compared to 'fake' coumarin plasma (●). Inhibitory capacity $I = 0.39$.

Discussion

Our data indicate that in Friuli plasma no inhibitory effect is present. The congenitally abnormal factor X and the abnormal factor X induced by vitamin K absence do not seem to behave similarly in a coagulation system. This is the more interesting as there exists a congenital factor II abnormality (prothrombin Barcelona) which up till now has appeared identical to the abnormal prothrombin induced by vitamin K absence [21].

The results of the kinetic studies are in agreement with immunological data [9]. In a cross-over electrophoresis or electrosyneresis system using anti-human factor X rabbit antiserum it could be demonstrated that coumarin plasma has two factor X bands [9]. One of these bands is equivalent to the normal factor X band, the second one, slightly more cathodic to it, is typical of anticoagulated plasma. In Friuli plasma only an apparently normal factor X band is visible.

All these data seem to indicate that factor X Friuli is different from the coumarin-induced abnormal form. The obvious discrepancy between the thrombotest dilution studies (fig. 1) and the specific experiment (fig. 2) is probably due to the fact that in a single factor deficiency or abnormality the dilution curve approach to the problem is of no value. It is known, in fact, that factor II, VII, and IX activities are normal in Friuli plasma [5-7].

Table I. Clotting times obtained in a specific experiment for Friuli plasma and 'fake' Friuli plasma

Friuli plasma			Fake Friuli plasma	
dilutions	1/X	clotting time, sec	1/X	clotting time, sec
normal plasma				
1/1	1.30	16.3	1.29	15.8
1/2	2.53	17.2	2.46	16.9
1/3	3.68	18.1	3.54	19.8
1/4	4.76	19.1	4.53	19.6
1/5	5.78	20.0	5.44	20.7
1/6	6.73	20.9	6.28	21.4
1/7	8.29	21.6	7.07	22.2
1/8	9.11	21.7	7.76	22.5
1/9	9.35	22.3	8.50	22.7
1/10	10.12	23.0	11.16	23.5

Table II. Clotting times obtained in a specific experiment for coumarin plasma and 'fake' coumarin plasma

Coumarin plasma			Fake coumarin plasma	
dilutions	1/X	clotting time, sec	1/X	clotting time, sec
normal plasma				
1/1	1.00	27.4	1.00	25.4
1/2	2.00	33.4	2.00	30.2
1/3	3.70	36.4	3.70	33.7
1/4	4.50	39.1	4.50	34.0
1/5	5.00	42.6	5.00	36.5
1/6	6.67	44.4	6.67	40.1
1/7	7.85	46.6	7.85	39.1
1/8	8.50	48.4	8.50	43.3
1/9	9.45	52.3	9.45	45.4
1/10	10.00	55.1	10.00	44.8

These observations are also in further agreement with the observation that the factor X level in Friuli plasma as estimated from the thrombotest system is practically identical to the level obtained with human brain thromboplastin, namely 5–10 % of normal [8, 11]. The assumption that

factor X Friuli is a structural, genetically determined factor X abnormality unaccompanied by the concomitant mutations of factor II, VII, and IX, and/or by the appearance of a PIVKA-like inhibitor, is further confirmed by the present study.
