Abstract: Acute tryptophan depletion (ATD), a method to temporarily lower central serotonin levels, has been used to study the functioning of the serotonergic system. Relatively recent studies that examined the effects of ATD on brain activation associated with cognitive and emotional processing in healthy volunteers are reviewed. An overview of the findings in healthy volunteers is important for the interpretation of the effect of ATD on brain activation in patients with an affective disorder, such as major depression. These studies show that during response control and negative feedback processing ATD modulates the BOLD response in the inferior/orbitofrontal cortex, the anterior cingulate cortex and the dorsomedial prefrontal cortex. During emotional processing, it is consistently found that ATD modulates the BOLD response in the amygdala. These brain regions also show abnormal activation in depressed patients.

However, at the moment it remains unclear if the changes induced by ATD are related to decreased basal serotonin (5-HT) release or the result of other biochemical changes that are mediated by ATD. Future studies should implement methodological improvements, explore the possibilities of new promising imaging techniques and expand investigations into the effects of ATD on basal 5-HT release and other biochemical mechanisms that might be modulated by ATD.

Keywords: Serotonin, acute tryptophan depletion, cognition, emotion, fMRI, PET, EEG, MEG.

1. INTRODUCTION

In this review, studies that examined the effects of acute tryptophan depletion (ATD), a method to temporarily lower central serotonin (5-HT), on brain activation associated with cognitive and emotional processing are discussed. To better understand the effects of ATD in psychiatric patients and in volunteers who are more vulnerable to the effects of ATD, such as people with a genetic risk to develop major depression, it is important to first establish the effects of ATD in healthy volunteers. In this review, only studies that tested healthy volunteers without a history of affective disorder are included. Furthermore, functional Magnetic Resonance Imaging (fMRI) studies that investigated the effects of ATD on brain correlates of cognitive and emotional processing started to appear in 2005; the first electroencephalogram (EEG) studies, sometimes combined with magnetoencephalogram (MEG), were first published only a few years earlier. In this review, these relatively recent articles will be discussed.

1.1. The Serotonergic System

5-HT is a monoamine that is widely distributed in different organ systems. Ninety percent of the 5-HT in the human body is believed to exist in the mucous membranes and the gastrointestinal tract, 8% in blood platelets and 2% in the central nervous system [1]. In the latter, 5-HT synthesizing neurons are primarily found in the rostral and the caudal raphe nuclei. Axons from neurons in the raphe nucleus form a neurotransmitter system with ascending and descending pathways throughout the brain and the spinal cord (see Fig. 1). The rostral raphe nuclei consist of a dual serotonergic fiber system that originates from distinct cell groups in the brain: i.e. the dorsal and medial nuclei raphe. The former projects to areas such as striatum, prefrontal cortex (PFC), thalamus, amygdala, temporal lobe and cerebellum, whereas the latter projects to similar areas in the neocortex but also to the hippocampus. Fibers from the caudal raphe nuclei project to the cerebellum and the spinal cord [2]. The

actions of 5-HT in these pathways are mediated by at least 7 receptor families that can also be further distinguished in several receptor subtypes [3]. Serotonin has been implicated in basic elements of behavioral and physiological control. Behavioral domains for which 5-HT is implicated include cognition, learning, sleep, social behavior, mood, impulsive emotion, appetite, anxiety and sexual behaviors. Physiological domains include thermoregulation, vasoconstriction, blood pressure and heart rate [1].

1.2. Acute Tryptophan Depletion

One method to examine the function of 5-HT neurotransmission in the brain is ATD. Since 5-HT cannot cross the blood-brain-barrier, its synthesis is dependent on its precursors, L-tryptophan (TRP) and 5-hydroxytryptophan (5-HTP). Namely, the amino acid TRP is first hydroxylated to 5-HTP, which is then synthesized to 5-HT [4]. By ingesting a mixture containing large neutral amino acids but that is deficient in L-tryptophan, a reliable and reversible lowering of specifically TRP concentrations in the blood can be found [5-7]. Central depletion after ingestion of the drink can be achieved by the effects of 1) increased protein synthesis incorporating TRP in organs outside the central nervous system that reduces the available precursor in the plasma [5], 2) a decrease in the ratio of TRP to other large neutral amino acids (LNAA) [8], and 3) competition between the large neutral amino acids that use the same amino acid carrier and TRP for transport into the central nervous system across the blood-brain-barrier [9].

In humans, ATD leads to a reduction of plasma TRP by 45-90%, which is reached around 4-7 hours after intake of the drink [6, 7]. Studies using rats have revealed that, next to a reduction in TRP ratios in the blood plasma, ATD also reduces TRP in several brain regions such as the hippocampus [10] and striatum [11]. Additionally, a 50% decline in 5-HT levels was found in the hippocampus, striatum, and cortex [11]. These findings extend to humans; ATD reduces cerebrospinal fluid TRP levels and decreases brain 5-HT synthesis [12, 13] demonstrating that ATD is a valid method for depleting 5-HT in the brain.

It must be noted that several variations in contents of amino acid mixtures have been used throughout the years. The mostly used drink is the so-called balanced amino acid mixture that is

based on the one described by Young *et al.* [14] and contains 5.5 g L-alanine, 4.9 g L-arginine, 2.7 g L-cysteine, 3.2 g L-lysine, 3.2 g L-histamine, 8 g L-isoleucine, 13.5 g L-leonine, 8.9 g L-lysine, 3.0 g methionine, 5.7 g L-phenylalanine, 12.2 g praline, 6.9 g L-serine, 6.9 g L-threonine, 6.9 g L-tyrosine, and 8.9 g L-valine. With this variant, the balanced drink contains the same amino acids to which 2.3 g TRP is added. At large two aspects have changed since this composition was reported: 1) the relative amount of TRP which was first 2.3% has increased and in many studies 4% TRP is added; 2) the total amount of amino acids has in many studies been reduced to 75 g using the same relative amounts of amino acids. In most imaging studies the 75 g or 100 g mixture was used, which reliably reduced plasma TRP.

1.3. Acute Tryptophan Depletion and Cognition

The most reliable effect of ATD on cognition is a modest impairment (5-10% reduction of test scores) of the consolidation of declarative episodic memory for verbal information, while other types of memory, such as semantic memory and working memory, seem to be less or not affected by ATD (for review see [15]). In addition, previous studies suggest that ATD impairs cognitive flexibility. Cognitive flexibility refers to the ability to switch between behavioral strategies, when changes in the environment lead to alterations in the outcome of actions. Previous research suggests that 5-HT is involved in cognitive flexibility. Animal research showed that low 5-HT leads to inflexible behavior during reversal learning and response inhibition [16-19]. In humans, ATD impaired the ability to perform a reversal shift in an intra and extra dimensional shift task [20, 21], impaired performance on a probabilistic reversal learning task [22] and impaired decision making [23] in healthy volunteers, although these effects were not consis-

tently found. Furthermore, previous studies suggest that ATD might not affect [24, 25] or might improve focused attention [26-28], measured by a response interference paradigm.

5-HT plays an important role not only in cognition but also in emotion regulation (for a review see [29]). Previous studies have shown that ATD affects for example subjective emotional state [30] and the perception and interpretation of emotional stimuli [31] in healthy volunteers with a vulnerability of the serotonergic system, such as females and participants with a previous history of affective disorder treated with serotonergic medications [32].

What are the biological mechanisms that underlie the effects of ATD on cognition and emotional processing? In other words, in what brain regions is the neuronal activation during cognitive performance and emotional regulation modulated by ATD? Based on the serotonergic projections it can be hypothesized that ATD primarily modulates the activity in the terminal regions, such as the temporal lobe, including the amygdala and the hippocampus, and the prefrontal cortex (see Fig. 1).

In this article, we will answer this question by reviewing ATD neuroimaging studies that investigated the effect of ATD on brain activation during cognitive and emotional task performance. Most studies discussed in this review used functional Magnetic Resonance Imaging (fMRI) to measure brain activity. The outcome measure of fMRI is the Blood Oxygen Level Dependent (BOLD) response. The BOLD response reflects a regional increase in oxygen levels as a result of regional brain activity. The fMRI studies discussed in this review tested participants in a 1.5 or a 3 Tesla MRI scanner. Some studies discussed in this review, used EEG or a combination of EEG and MEG to assess brain activation. EEG is the recording of electrical activity along the scalp produced by the firing of neurons within the brain. MEG is an imaging technique that measures the magnetic fields produced by electrical activity in the brain.

Studies that examined the effects of ATD on the auditory evoked potentials [33-36], somatosensory evoked potential [37] or quantitative EEG during rest [38] will not be discussed. The studies discussed (see also Table 1) examined the effects of ATD on brain activation during response conflict (including response inhibition and response interference), feedback processing, memory and selective attention, and the processing of emotional stimuli. These studies used a within-subject double-blind crossover design, unless otherwise mentioned, and participants were tested from around 5 hours after consuming the amino acids.

2. COGNITION

In this section, neuroimaging ATD studies will be discussed that investigated the effects of ATD on the BOLD signal during response inhibition and response interference. Response control requires the ability to overcome interference by adequately inhibiting a strong but inappropriate response tendency.

2.1. Response Control

Rubia *et al.* [39] investigated the effects of ATD on the BOLD response during response inhibition. Volunteers performed a Go/NoGo task in which arrows were presented that pointed to the left, to the right or upward. Participants had to respond with the left or right response button according to the direction of the arrow (Go trials), or had to inhibit their response when the arrow pointed upward (NoGo trials). ATD reduced the number of left-right errors, but did not affect performance on NoGo trials. Furthermore, no effects of ATD on subjective mood were found. FMRI analysis showed that ATD decreased the BOLD response during response inhibition (NoGo compared to Go trials) in the right orbital and inferior PFC. ATD increased the BOLD response during response inhibition in the right middle temporal gyrus, the left superior/middle and inferior temporal gyrus. The authors concluded that this data provides evidence for the hypothesis that 5-HT modulates

Table 1. An Overview of the Neuroimaging Studies that Examined the Effects of ATD on Brain Activation During Cognition and Emotional Processing

Study [ref] method	Cognitive Paradigm	Participants	Effects of ATD on Performance	FMRI Contrasts	Effects of ATD On Measure for Brain Activation	Other Results
Ahveninen <i>et al.</i> [63] EEG/MEG	Tone duration discrimination	n=13 (7 females)	In standards immediately after deviants, ATD increased the RT lag.		- Reduced N2 amplitude, elicited by task irrelevant deviants (ERP) - Increased MMNm peak latency (MEG)	
Ahveninen <i>et al.</i> [64] EEG/MEG	Counting deviant tones	n=13 (6 females)			N1 and P50 amplitude larger for attended than for unattended tones in the control but not in ATD condition. Increased P50 latency.	
Allen <i>et al.</i> [53] FMRI	1. Working memory task 2. Phonological verbal fluency task	n=10 (8 females)	None	1. 2-back - 0-back 2. Fluency - overtly expressing the word 'rest'.	1. Decreased BOLD signal in superior frontal cortex and increased signal in PCC. 2. Decreased signal in the precuneus and medial frontal gyrus.	
Cools <i>et al.</i> [67] FMRI	Emotional face task	n=12 (all males)	None	1. Fearful - fixation 2. Fearful - neutral faces 3. Fearful - happy faces	1. No effects 2. No effects 3. No effects	Threat sensitivity predicts the effect of ATD on the BOLD signal in the right amygdala for fearful - happy faces
Evers <i>et al.</i> [51] FMRI	1. Reversal learning task 2 Visual checkerboard task	n=12 (all males)	None	1a. Reversal switch errors - correct 1b. Other non-switch errors - correct 1c. Reversal switch errors - other non-switch errors 2. Visual stimulation - fixation	1a. Increased dmPFC signal 1b. Marginal increased dmPFC signal 1c. No effects 2. No effects	
Evers <i>et al.</i> [42] FMRI	Go/NoGo task	n=13 (all males)	None	1a. Correct Nogos - Correct Gos 1b. Negative - positive feedback 1c. Overall BOLD response	1a. No effects 1b. Decreased dmPFC signal 1c. No effects	
Evers <i>et al.</i> [49] FMRI	Combined cognitive an emotional Stroop task	n=15 (all females without a family history of major depression)	- Decreased interference for incongruent color (IC) compared to congruent color (CC) words - Increased number of errors for negative words	1. IC words 2. CC words 3. IC - CC words 4. Neutral (Neu) words 5. Positive (Pos) words 6. Negative (Neg) words 7. Pos - Neu words 8. Neg - Neu words 9. Overall BOLD response	1. Increased signal in precuneus and cuneus during CC words 2. Increased signal in the ACC during Stroop interference in the first Stroop block (IC-CC words) 3. No other effects	

(Table 1) Contd....

Study [ref] method	Cognitive Paradigm	Participants	Effects of ATD on Performance	FMRI Contrasts	Effects of ATD On Measure for Brain Activation	Other Results
Fusar-Poli <i>et al.</i> [70] FMRI	Emotional face task	n=10 (2 females)	ATD had no significant effect on gender discrimination	- Happy - neutral faces - Sad - neutral faces - Main effect of ATD independent of emotional valence	- Decreased signal in PCC and right lingual gyrus. Increased signal in left precentral and middle temporal gyrus - Decreased signal in the left lingual and right middle frontal gyrus. Increased signal the left inferior frontal gyrus and left cerebellum. - Decreased signal in the right medial/IFC, the PCC, the parietal and occipital cortex bilaterally, right hippocampus, claustrum and insula. Increased signal in left IFG.	ATD attenuated the signal to emotional (happy plus sad) faces in the left amygdala and increased the signal to emotional faces in the right amygdala.
Horacek <i>et al.</i> [48] FMRI	Stroop task	n=20 (10 females)	None	Incongruent - congruent trials	ATD increased the BOLD signal in the left IFC and the right medial frontal gyrus.	No gender differences were found
Hughes <i>et al.</i> [62] EEG	Oddball task	n=20 (all males)			ATD not did change the amplitude and latency of the N1P2 and P300 to target tones, omitted tones and frequent tones.	
Kähkönen <i>et al.</i> [65] EEG/MEG	Passive oddball	n=14 (7 females)			Increased amplitudes of frequency and duration MMN, and inter hemispheric latency difference of frequency MMNm. Increased P2m source signal and changed latency at auditory cortex.	
Lamar <i>et al.</i> [50] FMRI	Simon task	n=10 (females 55+; mean age 63)	None	Incongruent - congruent trials	Decreased signal in right ACC, right caudate/ putamen and left IFG. Increased signal in cerebellum, inferior parietal lobule regions, bilateral peristriate regions, right lingual gyrus, bilateral fusiform and parahippocampal gyrus.	
McAllister-Williams <i>et al.</i> [54] EEG	Episodic memory task	n=14 (all males)	- No effect on recognition - Impaired source memory - No effect ATD on RTs		- Waveforms more positive after ATD, with a greater effect at PZ than Fz. - No effects on the magnitude of the old/new effects (episodic retrieval).	
Roiser <i>et al.</i> [78] FMRI	Affective Go/NoGo task	n=20 (13 females)	None	- Emotional - neutral targets - Happy - sad targets - Emotional - neutral distracters - Happy - sad distracters	- Increased signal in left ventral putamen, left thalamus and left amygdala, right parahippocampal gyrus, parietal operculum, right anterior insula/ putamen. Decreased signal in right dorsolateral PFC. - Decreased signal in right STG. - Increased signal in right STG, left PCC, left posterior hippocampus, left dorsal caudate, right inferior temporal gyrus, right frontal operculum, right vIPFC, right caudate. Decreased signal in right dorsal ACC. - Decreased signal in PCC.	The STAI score (anxiety) after ATD correlates positively with the BOLD response in the right caudate for sad - happy distracters (more anxious greater response)

(Table 1) Contd....

Study [ref] method	Cognitive Paradigm	Participants	Effects of ATD on Performance	FMRI Contrasts	Effects of ATD On Measure for Brain Activation	Other Results
Rubia <i>et al.</i> [39] FMRI	Go/NoGo task	n=9 males and females	Reduction of the number of left-right errors.	1. Nogo - Go	1. Decreased signal in right orbital/IFC and in a more posterior right IFC focus extending into the precentral gyrus. Increased signal in right middle temporal gyrus and left middle-superior and inferior temporal gyri.	
Van der Veen <i>et al.</i> [56] FMRI	Visual verbal episodic memory task	n=11 (all males)	- Increased number of words associated with a positive feelings during encoding - Impaired recognition of positive words	1. Encoding: Words - Baseline 2. Recogn attempt: correctly rejected - baseline 3. Recogn success: correctly recognized - correctly rejected 4. Overall BOLD response	1. Decreased the hippocampal signal during encoding No other effects of ATD were found	
Van der Veen <i>et al.</i> [69] FMRI	Facial emotion perception task	14 females with and 19 without a family history of depression	None	1. Overall BOLD response 2. Intense - weak emotional expressions 3. Direct - incidental task 4. Fearful - happy faces	1. Increased right amygdala signal 2. None 3. None 4. None	Threat sensitivity correlated with the effect ATD in the right amygdala
Van der Veen <i>et al.</i> [52] EEG	Time estimation task	Cardiac n=13 ERP n=18 (all males)	None		Reduced cardiac deceleration after negative feedback, but no effect on FRN.	
Wang <i>et al.</i> [57] fMRI	Emotional oddball task.	n=13 (7 males)	- ATD induced a negative memory bias in the post-scan memory test: subjects recognized more negative pictures than neutral pictures. - Improved discrimination of new negative pictures.	1. Overall 2. Negative - (neutral+target) 3. Target - (negative + neutral)	1. Increased signal in the IFG, dmPFC and dorsal ACC. 2. Increased signal in the left orbitofrontal part of the IFG, dmPFC, bilateral angular gyrus, middle temporal cortex. 3. Decreased signal in the dmPFC (in default mode network: dmPFC, PCC, orbital-IFG).	After ATD, the memory score for both negative and neutral distracters was correlated with the signal in the visual cortex, fusiform gyrus, bilateral IFG, dorsal ACC and dmPFC. In the control session, only correlations in visual regions were found. No correlation of BOLD with negative memory bias was found after ATD.

(Table 1) Contd....

Study [ref] method	Cognitive Paradigm	Participants	Effects of ATD on Performance	FMRI Contrasts	Effects of ATD On Measure for Brain Activation	Other Results
Williams <i>et al</i> [71] FMRI	Emotional face task	n=8 for effect ATD on BOLD	- Overall, decreased response times. - Increased number of errors when processing specifically emotion shown in profile.	- Emotional judgment condition - baseline. - Interactions	- Decreased signal in left superior temporal sulcus. - Decreased signal in medial PFC, right temporal pole and OFC in front-view. Increased signal for faces in side-view in right superior temporal sulcus and left Broca. - Interaction ATD and emotion type in amygdala: ATD increased signal in right amygdala to side-viewed happy expressions; ATD increased signal in left amygdala to front-viewed fearful expressions	For all conditions - baseline correlations with plasma TRP were found in hippocampus, intraparietal sulcus, left insula, caudal part of ACC, left STG, bilateral posterior temporo-occipital junction.

Note. ACC=anterior cingulate cortex; ATD=acute tryptophan depletion; dmPFC=dorsomedial prefrontal cortex; IFC=inferior frontal cortex; OFC=orbitofrontal cortex; PCC=posterior cingulate cortex; PFC=prefrontal cortex; RT= reaction time; STG=superior temporal gyrus; vIPFC=ventrolateral prefrontal cortex.

activity of the inferior frontal cortex during motor response inhibition [40, 41].

Also Evers *et al.* [42] examined the effects of ATD on the BOLD response during response inhibition. Volunteers performed a modified Go/NoGo task in which a stream of letters was presented. Each correct response, i.e. a response on a Go trial and no response on a No-Go trial, was followed by a green square (positive feedback), and each incorrect response was followed by a red square (negative feedback). In addition, a response that was too slow (>500 ms) was also followed by negative feedback. ATD did not affect cognitive performance and no effects on mood were found. ATD did not change the overall BOLD response and did not change the BOLD response during response inhibition (correct NoGo trials compared to correct Go trials).

The study of Evers *et al.* [42] is in line with the majority of behavioral studies into the effect of ATD on response inhibition. These studies failed to find effects of ATD on motor response inhibition [e.g. 39, 43-47]. However, since fMRI is considered to be a more sensitive measure for changes in brain functioning than performance measures, the effect of ATD on brain functioning during response inhibition might have gone unnoticed in the behavioral studies. The different findings in the Rubia *et al.* [39] and the Evers *et al.* [42] study might be the result of differences in the response inhibition tasks that were used. The task used by Evers *et al.* [42] depended more on working memory and during the task feedback was provided whereas in the Rubia *et al.* [39] study the task was easier to perform and no feedback was given. Furthermore, in the Evers *et al.* [42] study only male volunteers were tested, while in the study of Rubia *et al.* [39] also females, who might be more vulnerable to the effects of ATD, were tested.

The effects of ATD on the BOLD response during response interference have been studied with the use of two different interference tasks, the Stroop and the Simon task. In a Stroop task, participants must override a predominant response tendency to read the meaning of the word and have to respond to the color of the ink. In a Simon task, participants must override a predominant response tendency to spatial information in order to respond to the direction indicated by small arrows.

Horacek *et al.* [48] studied the effects of ATD on the BOLD response during Stroop interference. In the MRI scanner, a modi-

fied Stroop task was performed that contained blocks of congruent and incongruent trials. After the scan session, the standard three card version of the Stroop task was used to investigate the effect of ATD on Stroop performance. ATD did not change Stroop performance. FMRI data showed that ATD increased the BOLD response in the left inferior frontal gyrus and the right medial frontal gyrus during incongruent (compared to congruent) trials.

Evers *et al.* [49] examined the effects of ATD on the BOLD response during a combined cognitive and emotional Stroop task (for results on the emotional Stroop, see section 2.2). Healthy females without a family history of major depression participated in this fMRI study. With regard to performance, ATD reduced the interference for incongruent (compared to congruent) trials. FMRI analyses showed that ATD did not change the overall BOLD response. Furthermore, it was shown that ATD increased the BOLD response in the left precuneus and cuneus during congruent color words, and increased the BOLD response in the anterior cingulate cortex in the first Stroop block during incongruent color (compared to congruent color) words.

Lamar *et al.* [50] studied the effects of ATD on the BOLD response during a Simon task in older adults. In this task arrows were presented that were either pointing to the left or the right while being projected to the same side of where they pointed (e.g. pointing to the right and being presented on the right side of the screen; congruent trials, 76%) or the opposite side of where they pointed (e.g. pointing to the right and being presented on the left side of the screen; incongruent trials, 12%). Additional arrows pointed at a slide angle (congruent trials; 12%). ATD decreased the mean state aggression scores but did not change performance on the Simon task. FMRI analyses showed that ATD decreased the BOLD response in the right anterior cingulate cortex, the left inferior frontal gyrus and the right striatum, particularly the caudate and putamen, and increased the BOLD response in the cerebellum bilaterally, the left inferior parietal lobule regions, the peristriae regions (cuneus and precuneus) bilaterally, the right lingual gyrus, the fusiform and parahippocampal gyrus bilaterally, during incongruent color (compared to congruent color) words.

These studies show that a number of regions are modulated by ATD. The results suggest that ATD increases the BOLD response in the PFC during incongruent trials in the Stroop task, and

increases the BOLD response in more posterior regions during incongruent trials in Simons task.

2.2. Feedback Processing

Receiving negative and positive feedback is important for behavioral rule learning such as in a reversal-learning task (reinforcement learning) and for performance monitoring. Previous studies have shown that the 5-HT system is implicated in punishment sensitivity (for review see [29]).

Evers *et al.* [51] investigated the effects of ATD on the BOLD response during a reversal-learning task. In this task, two stimuli were presented simultaneously and the participants had to respond by button press to the stimulus that was rewarded most of the time. When the participants had learned the stimulus-response rule, the rule was reversed, such that now the other stimulus was correct most of the time. After each trial, positive or negative feedback was given. Although ATD tended to increase the overall reaction time, no significant effect of ATD on performance was found. ATD did not change the overall BOLD response during the reversal learning task and did not change the task-related BOLD response during a visual checkerboard task (control task). Event-related analyses showed that ATD increased the BOLD response in the right dorsomedial PFC during trials in which negative feedback was followed by a behavioral switch (compared to baseline correct trials). Because the BOLD response was not changed after a behavioral switch and was only marginally increased after negative feedback, the authors argued that this suggests that ATD increases the BOLD response in the dorsomedial PFC during negative feedback.

Evers *et al.* [42] examined the effects of ATD on negative feedback in a Go/NoGo task (for task description see above). It was found that ATD decreased the BOLD response in the dorsomedial PFC during the receipt of negative feedback (compared to positive feedback).

Van der Veen *et al.* [52] investigated the effects of ATD on the feedback-related negativity. The feedback-related negativity is an event-related brain potential (ERP) component that is found at central electrodes (Cz) about 300 ms after the presentation of feedback. In this study, twenty healthy volunteers performed a time-estimation task, in which they estimated the duration of one second. After each response, feedback was given on how well they had estimated the duration. ATD did not change performance and did not change the amplitude of the ERPs related to positive and negative feedback. Although not a measure of brain functioning, ATD attenuated the phasic cardiac slowing to negative feedback.

In sum, the two BOLD fMRI studies [42, 51] suggest that ATD modulates the BOLD response in the dorsomedial PFC during negative feedback processing. An EEG study [52] did not show effects of ATD on electrical brain activity during the receipt of positive and negative feedback, but did show that ATD attenuated the cardiac slowing related to negative feedback.

2.3. Verbal Fluency

Allen *et al.* [53] examined the effects of ATD on the BOLD response during a working memory (see section 3 'memory' for results) and a phonological verbal fluency task. The verbal fluency task consisted of blocks in which the participants were asked to generate a word that starts with a given letter (task condition), or were asked to overtly articulate the word 'REST' (control condition). ATD decreased the BOLD response in the left medial frontal gyrus and in the precuneus during word generation (compared to word repetition). No ATD effects were found on mood and performance.

2.4. Memory

As noted above, one of the robust findings in ATD research has been that ATD impairs episodic memory consolidation rather than

other types of memory (for review see [15]). Several studies assessed the neuronal correlates of these findings.

McAllister-Williams and colleagues [54] examined the effects of ATD on brain activity during a verbal learning task. Participants were instructed to judge whether a spoken word was presented for the first time, or whether it was a repetition. This task assessed recognition of episodic memory. Furthermore, source memory was assessed by judging whether the word was spoken by a male or female voice. Only source memory was impaired after ATD, but not recognition per se [54]. Brain activity, as measured with late components of the event-related potential, was increased after ATD in posterior electrode locations in response to the processing of both new and repeated items. McAllister-Williams *et al.* [54] suggested that ATD may generally affect brain function, but is not related to specific aspects of retrieval. One interesting feature of these results is the increase in brain activity related to memory processes after ATD. Generally, a large amplitude on parietal electrodes is attributed to good memory performance (e.g. [55]).

Two recent studies investigated the effects of ATD on the BOLD response during memory [56, 57]. In the study by Van der Veen *et al.* [56], during encoding participants were presented with words that should be rated as giving a positive or a negative feeling. The participants gave a new/old judgment for the words in the recognition phase. More words were associated with a positive feeling after ATD than after the balanced drink in the encoding task. During recognition, however, ATD impaired performance for the positively associated words. The BOLD response in the hippocampus was decreased after ATD during encoding, whereas no changes were seen in BOLD response during the recognition phase. This suggests that ATD may affect both memory encoding and consolidation, because the latter process already starts during the encoding task (see also [27, 58]).

Wang *et al.* [57] examined the effects of ATD on the BOLD response during an emotional oddball task. In this task, participants had to respond to target pictures, but not to negative and neutral pictures that were presented as distracters. In a later recognition task, ATD improved discrimination for negative stimuli. This was accompanied by increased BOLD activity in the left orbital part of the IFG, dorsomedial PFC, and bilateral angular gyrus and middle-temporal cortex areas. However, several procedural flaws are present in this study such as an open-labeled design and the use of water as control drink instead of a balanced amino acid mixture, which makes the interpretation of the results complex. Therefore, these results should be interpreted with caution.

A last study that assessed memory effects of ATD was related to working memory [53]. Even though this type of memory has usually been related to dopamine function in frontal cortical areas [59], recently it was suggested that also 5-HT might play a role. Participants performed a 2-back task, in which they were instructed to indicate if the currently presented letter was the same as that presented two trials before. ATD did not affect the behavioral performance in this task as compared to the balanced drink, but the BOLD response was significantly decreased in the right superior/medial frontal gyrus. Furthermore, greater activity was found in the posterior cingulate gyrus, which was due to an attenuation of the response to the control task, a 0-back task.

In sum, imaging studies suggest that the episodic memory impairments are due to reduced activation of the hippocampus, even though the late positive component in the EEG suggested an improvement. Furthermore, working memory is somewhat impaired after ATD, which is associated with reduced BOLD activity in frontal areas.

2.5. Selective Attention

Attention is mediated by various regions in the brain including the PFC, the anterior cingulate cortex, and posterior parietal

cortices (e.g. [60, 61]). Given the fact that ATD has previously shown to improve selective attention processes [26, 27], and since the PFC and anterior cingulate regions were affected by ATD in the working memory study by Allen and colleagues [53], it is possible that the attention effects are mediated by these brain areas. However, to our knowledge no fMRI studies have yet been performed that are entirely dedicated to selective attention processes. Only a few EEG/MEG studies examined whether ATD can modulate brain activity related to attention.

Three studies used an active oddball task, in which frequent non-target tones were interspersed with infrequent target tones [62-64]. Hughes and co-workers [62] showed that none of the event-related potential components related to attention, namely the N1/P2 and the P300 in response to target tones, were affected by the ATD procedure. Also reaction times did not differ between the ATD and control condition. Unfortunately, they did not specify the task instructions.

In the first study by Ahveninen and colleagues [63], volunteers were presented with tones that did not only differ in stimulus frequency, but also duration. They were instructed to distinguish duration of the tones, but to ignore the frequency changes. ATD reduced the amplitude of the attention-related N2 component. In another study, Ahveninen *et al.* [64] combined an oddball task with a dichotic listening task. Participants were instructed to attend target tones in one of both ears and to silently count the number of target stimuli. ATD reduced the amplitude enhancement of P50 and N1 to the selectively attended tones [64].

One of the EEG/MEG studies on attention-related processes used a passive oddball [65]. In such a task, the target tone elicits a mismatch negativity component; a component occurring around 100-200 ms after stimulus presentation and that is related to pre-attentive sensory memory processes (see [66] for a review). Volunteers were presented with tones differing in frequency and duration while watching a silent video for distraction. ATD increased the amplitude of the mismatch negativity.

To summarize, early cortical brain responses were affected in three out of four attention-related experiments. However, the results here are counterintuitive to the previous behavioral studies. Where attention improvements were previously found [27], the EEG/MEG studies mainly showed reductions in attention-related components, normally indicating decreased attention. ATD, thus, does play a role in early perceptual processing, but future research should focus on the interplay between behavioral responses and brain activity during attention.

3. EMOTIONAL PROCESSING

In order to express appropriate emotions in interactions with other people it is necessary that emotions in other people are properly perceived and processed. An important cue in this respect is the emotional face expression. In this section studies using ATD and fMRI during processing of emotional faces and words will be reviewed.

3.1. Emotional Faces

Emotion is important for appropriate behavior in social contexts and is, among other things, dependent on the proper perception and further processing of emotion in other people. The most informative cue in this respect is the emotional face expression.

Cools *et al.* [67] examined the effects of ATD during the perception of emotional face expressions with an implicit emotional processing task. Volunteers were asked to categorize the gender of neutral, fearful and happy faces. The main finding of their study was that the effect of ATD on the BOLD response in the right amygdala in the contrast fearful minus happy faces correlated positively with a measure of threat sensitivity as determined with the BIS/BAS scales of Carver & White [68]. Higher threat

sensitivity scores were associated with a larger effect of ATD on the fear related amygdala response. Cools *et al.* [67] could not find any other effects of ATD on the BOLD signal and, furthermore, found that ATD did not affect performance scores and subjective mood ratings.

Van der Veen *et al.* [69] investigated the effects of ATD on the BOLD response during face processing with an explicit task or an implicit emotional processing task. Females with and without a family history of depression participated. This section will only focus on the results regarding the females without a family history of depression. The participants performed either a direct emotion categorization task or an indirect gender categorization task. In the gender task the participants had to select which of the two presented pictures that was most male and in the emotion task participants had to select the picture which was most emotional. Morphed faces were used, in which a male or female neutral face was morphed with a male or female emotional face. This resulted in two groups of faces with a weak emotional expression (10 or 30%) and two groups of faces with a strong emotional expression (70 or 90%). In this study fearful, disgusted, sad and happy faces were used, and most analyses focused on the difference between fearful and happy expressions. The main finding was that ATD enhanced the overall amygdala response to faces. Moreover, it was found that this effect was stronger in the contrast between fearful and happy faces. Additionally, van der Veen *et al.* [69] replicated the findings of Cools *et al.* [67] in showing that the right amygdala response to fearful faces correlated with threat sensitivity as measured with the BIS/BAS scales.

Fusar-Poli *et al.* [70] examined the effect of ATD on face processing with an implicit emotional processing task in ten volunteers. Fusar-Poli *et al.* [70] used happy, neutral and sad pictures. The main finding of this study was that independent of type of emotion, ATD attenuated the BOLD response in several cortical and subcortical areas and increased the BOLD response in the left inferior frontal gyrus. Furthermore, the authors reported a differential response in the right and left amygdala, i.e., the right showed an increased BOLD response after ATD, whereas the BOLD response in the left amygdala was attenuated after ATD. This effect was independent of type of expressed emotion. Finally, ATD did not affect performance and subjectively rated mood.

Williams *et al.* [71] studied the effects of ATD on the BOLD response during face processing with an explicit emotional processing task. In the used task the participants viewed front-viewed or side-viewed faces, expressing a strong (100% emotional), weak (50% emotional/50% neutral) emotion or no emotion (neutral) and were asked to decide whether the expression was neutral or emotional. ATD reduced activity independent of face view in the left superior temporal sulcus and the anterior cingulate gyrus. Modulatory effects of ATD were also found in other brain areas, but these were dependent on whether faces were front-viewed or side-viewed. Activity in the amygdala depended on both view type and emotion, i.e., right amygdala showed a stronger increase following ATD for viewing side-viewed happy faces, whereas the left amygdala showed a stronger increase following ATD for front-viewed fearful faces. ATD had an overall effect on performance leading to faster, but less accurate responses.

A common finding in all four studies is that ATD affects the BOLD response to emotional faces in the amygdala. All studies reported some kind of increased BOLD response in the amygdala in response to viewing negative face expressions. In three out of four studies the right amygdala response was more sensitive and the effect was also present independent of individual personality characteristics. Two studies reported a relation with subjectively reported threat sensitivity scores and the other two studies did not measure this trait. The sensitivity of the amygdala to ATD in the context of emotion processing fits with other lines of research that have repeatedly shown that the amygdala plays a central role in

emotion [72], that the amygdala is sensitive to genetically determined differences in the serotonin metabolism (e.g. [73]) and that amygdala function is disturbed in psychiatric illnesses characterized by large changes in emotion regulation such as major depression [74]. On the other hand, effects on other brain areas appeared to be very variable and are possibly dependent on the different task paradigms. It should be noted that the impact of most studies is limited by the relatively small number of participants that is included and that comparability is hampered by gender differences of the tested volunteers. On the other hand these weaknesses further stress the importance of the consistent effect of ATD on the BOLD response in the amygdala.

The overall finding that ATD increases the BOLD response in the amygdala is in line with fMRI studies that have shown that selective serotonergic reuptake inhibitors (SSRIs) reduced the amygdala response in emotion induction tasks [75-77]. This effect has been found in depressed patients who were treated for a couple of weeks [75, 76] or only pre-treated with a single dose [77]. So, it can be concluded that the amygdala is very sensitive to 5-HT interventions and that the ATD technique is powerful enough to highlight this sensitivity.

3.2. Emotional Words

Roiser *et al.* [78] investigated the effects of ATD on the BOLD response during emotional information processing with an affective Go/NoGo test. Volunteers completed a slightly modified ATD experiment. In this task words of different emotional valences (positive, negative or neutral) were presented, participants had to respond to each word of a particular valence and not respond to each word of the other valence, and words in all categories could either be target or distracter. The main finding of the study was that ATD increased BOLD responses in contrasts comparing emotional and neutral distracters or targets in a number of cortical and subcortical areas. For targets increases were found in left putamen, left thalamus, left amygdala, right parahippocampal gyrus, bilateral parietal operculum, and right anterior insula. For distracters increases were found in right superior temporal gyrus, left hippocampus, bilateral caudate nucleus, right inferior temporal gyrus and right ventrolateral PFC. Roiser *et al.* [78] also found an interesting relation with subjective mood, i.e., participants who reported more anxiousness following ATD also showed an increased BOLD response in the caudate in a contrast comparing negative and positive distracters. ATD only slightly affected performance in this task, leading to a somewhat stronger bias towards emotional stimuli (independent of valence) in the accuracy data.

Evers *et al.* [49] studied the effects of ATD on emotional information processing in an fMRI study in which participants performed a mixed emotional and cognitive Stroop task. Emotional (positive/negative), neutral and color (congruent/incongruent) words were presented in four different colors and participants had to respond to the color of the words and ignore the meaning of the word. Here, we will focus on the results regarding the emotional part of the Stroop task. The main finding was that ATD did not affect the BOLD response in any of the tested contrasts. Moreover, the relation with subjectively reported mood was also absent. The only effect of ATD in the emotional Stroop task in this study was a significant increase in the percentage of errors on negative words.

The results of the two reviewed studies are not very comparable which is possibly related to the large task differences (Stroop vs. Go/No-Go) and different experimental designs (standard amino acids mixture in tap water vs. low quantity in capsules). The Evers *et al.* [49] study could not find any effect of ATD on the BOLD response in any region and any contrast, whereas the Roiser *et al.* [78] study reported effects in a large number of regions and in a number of different contrasts. Besides the effect of ATD on many areas involved in emotion processing, Roiser *et al.* [78] also reported an increase the BOLD response in the amygdala which is

in line with the studies reviewed in the previous section which consistently showed a strong sensitivity of this brain region to ATD.

4. DISCUSSION

ATD neuroimaging studies showed that the BOLD response in some brain regions is changed more frequently than in other regions. The BOLD response in the inferior frontal cortex, the dorsomedial PFC, the anterior cingulate cortex, the orbitofrontal cortex and the amygdala is often found to be modulated by ATD. More specifically, ATD neuroimaging studies showed that during response control and negative feedback processing ATD modulates the BOLD response in the inferior/orbitofrontal, the anterior cingulate cortex and the dorsomedial PFC. The effects of ATD on brain activation during memory and selective attention tasks are less clear. Only few studies into the effects of ATD on memory-related brain activation have been carried out, and the ones that were carried out studied different memory processes. No ATD neuroimaging study was entirely dedicated to selective attention. During emotional processing, it was shown that ATD modulates the BOLD response in the amygdala.

Major depression has been related to disturbances of the 5-HT system, such as lower levels of central 5-HT [79]. It has been shown that ATD leads to a relapse in 50-60% of selective serotonin reuptake inhibitor (SSRI) treated remitted depressed patients (for review see [32]). Furthermore, ATD induced depressed mood in healthy people who are more vulnerable to develop major depression, such as people with the s/s genotype for the 5-HT transport (SERT) and people with a positive family history of affective disorder [32, 80-85]. In line with cognitive disturbances found in depressed patients, ATD impaired memory consolidation [15] and cognitive flexibility [20, 21] in healthy volunteers. These findings suggest that ATD might induce a state in healthy volunteers that resembles major depression, although in a much milder form. Interestingly, the regions that have found to be modulated by ATD, such as the dorsomedial PFC, the orbitofrontal cortex, and the amygdala, are found to be abnormally activated in depressed patients. Previous studies showed reduced glucose metabolism and reduced gray matter in these regions in depressed patients (for review see [86]).

4.1. The Effect of ATD on the 5-HT System

To clarify the influence of ATD on the functioning of the 5-HT system, previous studies have investigated the effect of ATD on 5-HT synthesis, the 5-HT transporter and different 5-HT receptor types. The results of a positron emission tomography (PET) study indicate that ATD decreases the synthesis of 5-HT throughout much of the cerebral cortex of healthy volunteers [12]. In addition, it was shown that women had a lower baseline 5-HT synthesis than men and that ATD decreased 5-HT synthesis more in women than in men. In response to criticisms of the used methods, the authors improved the methods and replicated the finding that in women the 5-HT synthesis is lower than in men [87]. However, the effects of ATD on 5-HT synthesis were not reexamined.

Animal research suggests that the location of the 5-HT transporter (SERT) is affected by the levels of synaptic, i.e. extracellular 5-HT [88,89]. Decreased synaptic levels of 5-HT are thought to translocate the SERT away from the plasma membrane resulting in decreased SERT density in the plasma membrane and therefore decreased binding of a SERT tracer. Talbot *et al.* [90] therefore put forward the hypothesis that changes in extracellular 5-HT will change the binding potential of a radiotracer to image the SERT. However, they failed to find effects of ATD on the binding potential of the SERT tracer ¹¹C-DASB, and concluded that the SERT tracer binding is not sensitive to detect decreased levels of synaptic 5-HT associated with ATD. The alternative explanation that ATD does not alter synaptic 5-HT is considered to be unlikely since animal studies showed that brain 5-HT is depleted after ATD.

Praschak-Rieder *et al.* [91] examined the effect of ATD on the affinity and density of SERT, since changes in affinity and density of the SERT could be a compensatory mechanism to maintain sufficient extracellular levels of 5-HT after ATD. The results showed no effects of ATD on the regional SERT tracer (11C-DASB) binding potential, which suggests that ATD does not alter SERT affinity and density.

Both Udo de Haes *et al.* [92] and Rainer *et al.* [93] investigated the effect of ATD on the binding potential of a tracer for 5-HT_{1A} receptors in healthy volunteers. Both studies failed to find consistent effects of ATD on the binding of the 5-HT_{1A} tracer. Yatham *et al.* [94] examined the amount of 5-HT₂ receptor binding of a radioactive tracer after ATD compared to placebo in healthy volunteers. They showed decreased 5-HT₂ receptor binding in the left fusiform gyrus, the left insula, the left superior temporal gyrus, and the left superior frontal gyrus. This decrease in binding potential, which is indicative for increased 5-HT levels, was not expected. The authors argued that the data might indicate that decreased levels of 5-HT trigger an adaptive response, such as reduced density of the number of 5-HT₂ receptors, to protect against depressive symptoms.

Chair *et al.* [95] studied the effects of ATD on the 5-HT_{1A} and 5-HT_{2A} receptor binding (in-vitro) in the rat brain. They showed that ATD significantly reduced somatodendritic 5-HT_{1A} binding in the dorsal raphe by 14%. However, no changes in postsynaptic 5-HT_{1A} reduction were found in the cortex and the hippocampus. In line with Yatham *et al.* [94], Chair *et al.* [95] showed that 5-HT_{2A} binding in the cortex was reduced after ATD. However this reduction was not significant, which might be related to the greater variability in in-vitro radioligand binding compared to in-vivo PET.

In sum, these studies suggest that ATD decreases the synthesis of 5-HT in the brain, does not affect the density or affinity of the SERT, decreases the density of the 5-HT₂ receptor, and might have an effect on the somatodendritic 5-HT_{1A} receptors.

4.2. The Effect of ATD Explained by the Effect on Other Neurotransmitter Systems

The 5-HT, norepinephrine (NE), dopamine (DA), and acetylcholine (ACh) neurotransmitter systems largely overlap in terms of their being widespread in their anatomical organization. Not only are the origination brain stem nuclei interconnected, these systems also have overlapping terminal fields and innervation patterns [2]. Briand *et al.* [96] stressed the importance to focus on the regulatory and functional interactions between these systems, rather than studying these neurotransmitter systems in isolation.

5-HT is known to have inhibitory influences on NE, ACh, and DA turnover [97]. In particular, an increased relative influence of NE transmission brought about by decreased 5-HT turnover might explain the positive effects of ATD on focused attention. Importantly, it must be noted that if in an experiment, independent variable X is manipulated leading to a change in dependent variable Y, experimental methodology only permits conclusions attributing the change in Y to varying levels of X. Suppose that the manipulation of X induces changes in Y, but these are known to be actually accomplished by Z, in such a way that it would have been more appropriate to manipulate Z rather than X. One should attempt to either manipulate or control Z or measure its known indicator(s). According to experimental methodology, one may only speculate but not conclude about the potential mediating influence of Z. In the example above, X refers to 5-HT, Y to cognitive performance or neuroimaging variables, and Z refers primarily to NE. We would like to stress that drawing conclusions about Z on the basis of experiments in which X is systematically varied and changes in Y are measured, are in general not permitted. So in the above example one may only speculate about the role of NE in the effects of ATD on focused attention.

Previous studies suggest that ATD does not affect DA levels. It was shown that ATD did not change cerebrospinal fluid levels of tyrosine [98], plasma, cerebrospinal fluid and brain levels of DA metabolites [11, 26, 98], the concentration of DA in the brain [99], and the DA efflux in the medial PFC [100]. Furthermore, ATD did not change the concentration of NE levels in the brain [99]. To the best of our knowledge no study so far has investigated the effect of ATD on ACh release. Interestingly, Lieben *et al.* [101] showed that metrifonate, an acetylcholinesterase inhibitor, which increases ACh in the synapse, reversed the memory deficits that were induced by TRP depletion in rats. These findings suggest that the effects of ATD might be due to specific effects on the 5-HT system.

4.3. Interpretation of the Results of the ATD Neuroimaging Studies

A number of factors make the interpretation of the effect of ATD on the BOLD response not straightforward.

Confounding Factors

A number of known confounding factors, such as personality and genetic 5-HT vulnerability, are not consistently taken into account in these ATD neuroimaging studies. It has been shown that personality characteristics interact with the effect of ATD. For example, self reported threat sensitivity correlated positively with the ATD-induced increase in BOLD response in the amygdala [67] and impulsivity correlated negatively with ATD-induced reward-related speeding on a reaction time task [44]. In addition, participants with an increased vulnerability of the 5-HT system are more sensitive for the effects of ATD. In participants with two small alleles of the 5-HT transporter linked polymorphic region, but not in participants with two long alleles, ATD decreased motivationally speeded action [102], and a stronger bias toward choosing the certain option in a decision making task was found in participants with two small alleles [103]. Furthermore, ATD impaired immediate and delayed recall on an episodic verbal memory tasks more in females than in males [104]. To improve the interpretation of the findings of ATD studies, factors that are known to modulate the effect of ATD should be controlled for.

Pharmacological Neuroimaging

Pharmacological functional Magnetic Resonance Imaging (ph-fMRI) is a method that enables the measurement of changes in brain activation evoked by drug treatment. BOLD fMRI, the method mostly used, does not measure neural activity directly, but relies on a cascade of physiological events linking neural activity to the generation of the MRI signal. Most ph-fMRI studies performed so far have interpreted changes in BOLD signal as changes in "brain activation", ignoring the potential confounds that can arise through drug-induced modulation on the events downstream of the neural activity [105]. Since drug treatment can change the neurovascular response, a drug has the potential to change the BOLD response without changing neural activity. Therefore methodological improvements are needed to interpret changes in BOLD signal.

5-HT Mediated Instead of 5-HT Induced

There is still no direct evidence that ATD alters brain 5-HT release, i.e. that ATD actually alters the functional activity of the 5-HT neurons [106]. It has been shown that ATD reduces plasma TRP, brain TRP, 5-HT and 5-HIAA in rats (e.g. [5]), and reduces plasma TRP, plasma ratio TRP/LNAA, TRP and 5-hydroxyindoleacetic acid (5-HIAA; 5-HT metabolite) levels in cerebrospinal fluid (e.g. [107]), and synthesis of brain 5-HT in humans [12]. However, these measures are only estimates for the 5-HT neuronal activity. It is possible that in the absence of new 5-HT synthesis, 5-HT function can be largely maintained from 5-HT being recycled from the synapse into the presynaptic cell. It has been shown that without an initial increase in 5-HT concentration, basal 5-HT release in the medial PFC of the rat appeared not to be affected by

ATD [100]. Moreover, decreased levels in whole brain 5-HT and 5-HIAA levels in the cat did not parallel changes in functional activity of 5-HT containing raphe nucleus cells [108]. These findings suggest that other mechanisms might be responsible for the effects of ATD on behavior, mood and the underlying brain activation [106].

Furthermore, it could be argued that the ATD neuroimaging studies should have tested the participants at a later moment. Namely, at the moment that not only the levels of brain TRP and 5-HT synthesis have decreased, but also the still available brain 5-HT is released and metabolized. Brain 5-HT turnover could be accelerated by experimental manipulations that lead to increased 5-HT release, such as exposure to uncontrollable stress [109, 110].

Van Donkelaar *et al.* [111, 112] investigated potential mechanisms by which ATD could exert its effects. It was shown that ATD alters the relation between cerebral blood flow (CBF) and glucose metabolism independent of central 5-HT [112]. Furthermore, Talbot and Cooper [113] investigated the effects of ATD on the regional CBF in healthy males during rest. After removal of the variance in regional CBF associated with mood, ATD reduced the CBF in the dorsal anterior cingulate cortex, and increased the CBF in the left cuneus, lingual gyrus and the cerebellum. Interestingly, Evers *et al.* [51] showed that ATD did not affect the task-related BOLD response during a visual checker-board task (control task), suggesting that ATD does not induce vascular effects that lead to a global increase of task-related activation. Two studies [111, 114] showed that brain-derived neurotrophic factor (BDNF) might play a role in the effects of ATD. In contrast, the study of Chair *et al.* [115] showed that plasma or central BDNF protein levels in the hippocampus and midbrain were not altered by ATD. Furthermore, based on a study of D'Souza *et al.* [116], Chair *et al.* [115] speculated that the effects of ATD on the 5-HT_{2A} receptor might be mediated by corticosterone. In addition, Riedel *et al.* [117] showed that ATD blocked the stress-induced cortisol response which is indeed partly 5-HT_{2A} mediated. ATD also blocked the association between cortisol and memory impairment. These findings suggest that ATD-induced alterations go beyond a straightforward dysfunction of the 5-HT system. Also changes seen in depressed patients could be caused by other factors not induced but mediated by 5-HT levels.

Some findings that were discussed might make us wonder if the effects of ATD are indeed mediated by changes in activity of the 5-HT neurons. Firstly, it was shown that ATD modulated the BOLD response in the dorsomedial PFC during negative feedback processing. However, no effects of ATD were found on the feedback related negativity at the Cz. Interestingly, ATD affected cardiac slowing. It might be speculated that changes in cardiac functioning might influence CBF and thereby change the BOLD response. Secondly, if ATD affects basal 5-HT release, which strongly affects DA release, effects of ATD on DA levels are expected. However, it was repeatedly shown that ATD did not affect DA release.

4.4. Future Research

In this section we will give some suggestions for the improvement of future ATD neuroimaging studies. These improvements are necessary to be able to reliably interpret the effects of ATD on brain functioning.

When BOLD fMRI is used to examine the effects of ATD on brain activation, methodological improvements are needed for a better interpretation of changes in BOLD response. Examples of methodological improvements are the inclusion of one or more control tasks, the recording of neuroendocrine (e.g. cortisol and prolactin) and physiological parameters (e.g. heart rate, breathing rate) during scanning assessing drug-induced changes in resting state BOLD signal and resting state regional CBF [105]. These methods are at the moment only sparsely applied.

It can be said in addition for all ATD studies that there are too many studies that lack an active comparator condition. This may bias the results and their interpretations considerably. Besides using a control mixture, the recommendation is therefore to always include one other condition in which another amino acid is omitted, but which is not hypothesized to influence the target behavior, or which is hypothesized to influence another behavior.

Since BOLD fMRI is not a good method to measure drug-induced changes, other functional brain imaging methods might turn out to be more reliable. Arterial spin labeling [118], which measures CBF, and calibrated fMRI [119], which estimates cerebral metabolic rate of oxygen (CMRO₂) are two new and promising methods. Although also indirect measures of neural activity, CBF and CMRO₂ are more directly related to neural activity and less confounded by overall changes in the neurovascular coupling than the BOLD response. We therefore advise future studies to make use of these methods.

More research into the effects of ATD on basal 5-HT release is necessary. Studies are needed that measure the amount of 5-HT efflux in the entire cortex and studies that extend this type of research to animals with a vulnerable 5-HT system will be important [99].

Van Donkelaar *et al.* [105] suggested that other brain mechanisms might be responsible for the effects of ATD on the BOLD response, and investigated the effects of ATD on BDNF and CBF. Future studies should expand the research into other brain mechanisms that might be modulated by ATD.

CONCLUSIONS

ATD neuroimaging studies show changes in the BOLD response that resemble the abnormal patterns seen in depressed patients, such as in the PFC and limbic regions. However, at the moment it remains unclear if these changes are related to changes in basal 5-HT release, related to indirect effects of 5-HT on the level of other neurotransmitters, such as ACh and NE, or are related to other biochemical changes that are mediated by ATD.
