Will the skill-premium in the Netherlands rise in the next decades?

A. Dupuy

Faculty of Economics and Business Administration, Research Centre for Education and the Labour Market, Maastricht University, P. O. Box 616, NL-6200 MD, The Netherlands
E-mail: a.dupuy@roa.unimaas.nl

While the skill-premium has been rising sharply in the US and the UK for 20 years, the Dutch skill-premium decreased for much of that period and only started to rise in the early 90s. In this article, we investigate whether the Dutch skill-premium will rise in the next decades. To answer this question, we forecast the skill-premium using the Katz and Murphy (1992) and the Krusell et al. (2000) models. The Katz and Murphy model (KM) explains demand shifts by skill-biased technological change in unobservable variables captured by a time trend. In contrast, the Krusell et al. model (KORV) explains demand shifts by (observable) changes in the capital stock under a capital-skill complementarity technology. The results show that while the KM model predicts that the skill-premium will have increased by 30% in 2020, based on realistic predictions of the stock of capital, the KORV model predicts that the skill-premium will remain between $-5$ and $+5\%$ of its 1996 level.

I. Introduction

In recent decades, the skill-premium has been rising sharply in the US and the UK. In contrast, in most continental European countries the skill-premium has been decreasing or stagnating (Freeman and Katz, 1994; Nickell and Bell, 1996) until recent years. However, in the 90s, the skill-premium started rising in Germany and the Netherlands for instance, see Acemoglu (2003), Leuven and Oosterbeek (2000) and Jacobs (2004). At the same time, all developed countries have experienced a steadily increasing relative supply of skilled workers. There is a fairly documented literature that explains the rise in the US skill-premium by continuous shifts in the relative demand for skilled workers of a magnitude off-setting the increase in the relative supply (Katz and Murphy, 1992).

In the literature related to the rising skill-premium, two main explanations\(^1\) are often put forward.

\(^1\) A third explanation put forward in the literature is the increasing international trade. However, several arguments (e.g. same timing in the trade and nontrade sectors) against this explanation are raised (Johnson, 1997; Acemoglu, 2002). A fourth explanation put forward is the institutional change (DiNardo et al., 1996; Lee 1999). Acemoglu (2002) raises serious arguments against this explanation. Regarding the minimum wage: the decrease of the minimum wage cannot explain the rise in wage dispersion observed above the median of the wage distribution. Regarding the unions: wrong timing of deunionization and wage inequality, and inconsistancy between the unionization and rising wage inequality in Canada through the 70s and 80s.
The skill-biased technological change (SBTC) explanation, led by Katz and Murphy (1992), Bound and Johnson (1992), Berman et al. (1994) and Autor et al. (1998) and Acemoglu (2002) is the most dominant in the literature. The argument reads as follows. New technologies are relatively more complementary with skilled workers than with unskilled workers. These new technologies when used in the production process therefore shift the relative demand for skilled workers upward. The SBTC effects on the skill-premium are captured in the Katz and Murphy (1992) model (KM model from now on) by regressing the log skill-premium on a time trend. The second explanation has its roots in the capital-skill complementarity in production. Skilled workers are more complementary to capital than unskilled workers, so that a decrease in the price of capital shifts the relative demand of skilled workers upward (Krusell et al., 2000; Beaudry and Green, 2003). The capital-skill complementarity effects on the skill-premium are captured in the Krusell et al. (2000) model (KORV model from now on) by regressing the log skill-premium on the log capital stock.

Although the Netherlands experienced a decrease in the skill-premium through the 70s and 80s, the skill-premium increased notably since the mid 90s (Leuven and Oosterbeek, 2000; Jacobs, 2004). The major reason for this is the slower growth of the skill supply observed since the beginning of 90s. This raises the question whether the Dutch skill-premium will continue to increase in the years to come like it did in the US for the last 20 years and whether the race between schooling and technology is lost by schooling (Tinbergen, 1975)?

To investigate this question we forecast the skill-premium to 2020 using the KM model, where skill-biased technological change is captured by a time trend and the KORV model, where SBTC are brought about by (observable) changes in the capital stock under a capital-skill complementarity technology. We first estimate parameters of the two models on the span 1969 to 1996 for the Netherlands. Using predictions for the relative skill supply, a first set of forecasts is derived from the Katz and Murphy (1992) model. These forecasts are similar to those derived by Jacobs (2004). A second set of forecasts is generated from the Krusell et al. (2000) model. Four scenarios of the change in the stock of capital are considered. In the first scenario, the stock of capital will increase at an annual rate of 10% (equivalent to the highest growth rate in five successive years (1982–1986) observed during the last decades), in the second scenario, the stock of capital equipment will increase at an annual rate of 6% (equivalent to the growth rate observed between 1969 and 1996), in a third scenario, it grows at 3% per year (its growth rate in the last 5 years observed, 1992–1996). In the fourth scenario, we use recent forecasts made by the CPB Netherlands Bureau for Economic Policy Analysis indicating that the stock of capital will rise at an annual rate of 1.6% through 2010.

The article is organized as follows. In Section II we present the KM and KORV model. In Section III we discuss the data used for empirical analysis. In Section IV we present the empirical results. Section V concludes.

II. The Model

In this article we analyse the schedule of the skill-premium in the Netherlands. The analysis rests on a general aggregate production function that nests the two sources of changes in the skill-premium: the substitution effect that arises from shifts in the relative supply of skilled labour and the demand shift effect due to skill-biased technological change. We distinguish SBTC brought about by unobservable variables and captured by a time trend, the KM model, from SBTC brought about by (observable) changes in the price of capital when the production technology is characterized by capital-skill complementarity, the KORV model.

Let the aggregate production function be

\[ Y_t = F(\theta_{st} L_{st}, \theta_{ut} L_{ut}, K_t), \]

where \( L_{st} \) and \( L_{ut} \) represent respectively the supply of skilled and unskilled labour, \( \theta_{st} \) and \( \theta_{ut} \) represent respectively the

---

\(^2\) See, e.g. Rosen (1968), Griliches (1969), Grant (1979) and Hamermesh (1993).

\(^3\) The explanation of increasing skill premium by the capital-skill complementarity has often been rejected because of its apparent inconsistency with a constant share of capital in the economy. However, though an aggregate production function with a unitary elasticity of substitution between capital and labour (aggregate of skilled and unskilled labour) ensures the constancy of the share of capital, there are more flexible forms of aggregate production function satisfying the postulate of the constant share of capital. Indeed, a production function with a greater-than-unity elasticity of substitution accompanied by a labour augmenting technological change would be consistent with constant shares of labour and capital, see e.g. Brown and De Cani (1963), Kennedy (1964), David and van de Klundert (1965), Sato (1970) and Yuhn (1991).

Will the skill-premium in the Netherlands rise in the next decades?

The possibility of skilled and unskilled labour augmenting factors, i.e. skill-biased technological change brought about by unobservable variables, and \( K_t \) is the stock of capital at time \( t \).

The equation on which we base our empirical investigation is derived from the marginal product conditions for wages, the assumption of competitive input markets, \( \partial F / \partial L_j = w_j \) and \( \partial F / \partial K = r \), that is

\[
w_{st} = \frac{\theta_{st} \partial F}{\partial L_{st}} \quad (1)
\]

\[
w_{ut} = \frac{\theta_{ut} \partial F}{\partial L_{ut}} \quad (2)
\]

where \( w_j \) is the wage rate of labour \( j, j = \{u, s\} \).

The log-linear approximation of Equations 1 and 2 can be written as:

\[
\ln w_{st} = \alpha_0 + \alpha_s \ln (\theta_{ss} L_{st}) + \alpha_u \ln (\theta_{uu} L_{ut}) + \alpha_K \ln K_t + \ln \theta_{st}
\]

\[
\ln w_{ut} = \beta_0 + \beta_s \ln (\theta_{ss} L_{st}) + \beta_u \ln (\theta_{uu} L_{ut}) + \beta_K \ln K_t + \ln \theta_{ut}
\]

Using Equations 3 and 4, the log skill-premium \( \pi_t \equiv \ln w_{st} - \ln w_{ut} \) can then be written as:

\[
\pi_t = \alpha_0 - \beta_0 + (1 + \alpha_s - \beta_s) \ln \theta_{st} + (\alpha_u - \beta_u - 1) \ln \theta_{ut} + (\alpha_u - \beta_u) \ln L_{ut} + (\alpha_K - \beta_K) \ln K_t \]

\[
+ (\alpha_s - \beta_s) \ln L_{st} + (\alpha_u - \beta_u - 1) \ln L_{ut} + (\alpha_K - \beta_K) \ln K_t + \ln \theta_{st}
\]

\[
(5)
\]

Note that for \( \alpha_s - \beta_s = \beta_u - \alpha_u \) we have:

\[
\pi_t = \alpha_0 - \beta_0 + (1 + \alpha_s - \beta_s) \ln \theta_{st} + (\alpha_u - \beta_u - 1) \ln \theta_{ut} + (\alpha_u - \beta_u) \ln L_{ut} + (\alpha_K - \beta_K) \ln K_t
\]

\[
+ (\alpha_s - \beta_s) \ln L_{st} + (\alpha_u - \beta_u - 1) \ln L_{ut} + (\alpha_K - \beta_K) \ln K_t
\]

\[
(6)
\]

The term in second row of Equation 5 captures the effect of skilled-biased technological change brought about by unobservable variables. The term in the third row captures the substitution effect induced by shifts in the relative skill supply and the term in the last row captures observable SBTC via the capital-skill complementarity.

The capital-skill complementarity effect on the skill-premium can further be decomposed into an impulse due to changes in the stock of capital, i.e. \( d \ln K_t \) and a multiplicative effect depending on the technological parameters of substitution between capital and skilled and unskilled labour. Since capital and unskilled workers are usually strong substitutes, we expect \( \beta_K < 0 \). In contrast, we expect capital and skilled labour to be complementary and therefore \( \alpha_K > 0 \).

Imposing \( (\alpha_K - \beta_K) = 0 \) in Equation 6 we obtain the KM model.

**KM model**

\[
\pi_t = \gamma_0 + \gamma_1 \ln \frac{L_{st}}{L_{ut}} + \gamma_2 t + \varepsilon_t
\]

where \( (1 + \alpha_s - \beta_s) \ln (\theta_{st})/(\theta_{ut}) = \gamma_2 t \), \( (\alpha_s - \beta_s) = \gamma_1 \) and \( \alpha_0 = \beta_0 = \gamma_0 \), and the elasticity of substitution between skilled and unskilled labour is \( \sigma = 1/\gamma_1 \).

Imposing \( \ln (\theta_{st})/(\theta_{ut}) = \delta \) to be constant through time in Equation 6, we obtain the KORV model.

**KORV model**

\[
\pi_t = \gamma'_0 + \gamma'_1 \ln \frac{L_{st}}{L_{ut}} + \gamma_5 \ln K_t + \varepsilon'_t
\]

where \( (\alpha_K - \beta_K) = \gamma_5 \), \( (\alpha_s - \beta_s) = \gamma'_1 \) and \( \alpha_0 - \beta_0 = \gamma'_0 \).

### III. The Data

The data we use consists of annual time-series of capital and labour for the Dutch economy between 1969 and 1996.\(^5\) We use the National accounts time-series collected by Statistics Netherlands, CBS (1999). The data consists of capital and labour accounts. The capital accounts data contains five investment series. Investment in machines, transports, computers, materials and the aggregate of these four investments that form investments in equipment are available in current prices. We make use of the respective price-index for the period 1969 to 1996 to deflate the five series of investment and obtain measures of investments in 1969 prices. The stock of capital for the five series is then calculated using the perpetual inventory method. The capital stock in 1969 is set to the investment level in 1969. We recursively construct the stock of capital the next period using investment and a depreciation ratio of 0.05 for equipment, machines and transports and 0.10 for materials and 0.15 for computers.\(^6\) In the remaining part of this study we use the series on the stock of capital equipment. The series of capital equipment are normalized to 1 in 1969. As illustrated in Fig. 1 the stock of capital

\(^5\) The data can be obtained from the author's website, http://www.fdewb.unimaas.nl/roa. More recent data was not available at the time the analyses were done.

\(^6\) Other plausible rates of depreciation did not alter the results significantly.
equipment increases almost steadily throughout the period at a yearly rate of 6%.

Since we are interested in developments in the skill-premium, we distinguish between skilled and unskilled labour. We use the time-series collected by Statistics Netherlands (CBS). We define low-skilled workers by workers with primary or secondary education and skilled workers by higher educated workers. The relative supply of skilled workers is the ratio of the number of skilled workers, expressed in man-years, to the number of unskilled workers, also expressed in man-years. Wages are based on gross hourly wages and we define the skill-premium as the ratio of the wages of skilled workers and unskilled workers. The supply of both skilled and unskilled workers is normalized to 1 in 1969.

The data indicates that the supply of skilled workers has been multiplied by a factor 3.5 in the period of observation while the supply of unskilled workers remained fairly stable, as shown in Fig. 1.

As indicated in Fig. 2, the skill-premium decreases, first moderately through 1979 at an annual rate of 0.6%, then sharply between 1979 and 1985 at an annual rate of 2.8%, and remains fairly stable to 1992. From 1992 to 1996, the skill-premium slightly increases at an annual rate of 0.4%.

IV. Empirical Results

Estimation of the KM and KORV models

Our empirical objective is to get estimates of the parameters of the KM and KORV models to make forecasts of the skill-premium in the Netherlands. This could be done by ordinary least squarers (OLS) estimations of Equations 7 and 8. However, when estimating both parameters $g_1$ and $g_2$ in Equation 7 or $g_0$ and $g_3$ in Equation 8 simultaneously, the parameters have the wrong sign due to strong multicollinearity in the series. We therefore regress the skill-premium series on the relative supply of skilled labour at given plausible time trend parameters (KM model) or capital-skill complementarity parameters (KORV model) as suggested by Katz and Murphy (1992) and Jacobs (2004).

The estimation results reported in Table 1 indicate that at comparable elasticities of

---

7 The labour series and wage series we use are simply obtained by aggregating $l_u = l_{pr} + l_{se}$ for unskilled labour (where $l_{pr}$ and $l_{se}$ are respectively the number of man-year with primary and secondary education and weighting $w_u = (l_{pr}w_{pr} + l_{se}w_{se})/l_u$ for the unskilled wage.
substitution, both the model with time trend and the model with capital equipment explain roughly the same percentage of the variance in the skill-premium schedule. The fit of both models is globally equivalent as indicated by the adjusted $R^2$ statistics and illustrated in Fig. 2. Both models seem to be equally suited to forecast ex post the skill-premium in the Netherlands. It is empirically impossible to decide which model should be preferred, choosing in favour of the KM or the KORV model, therefore, depends merely on one’s economic belief on whether capital and skilled labour are complementary in production or not.

To compare the magnitude of the capital-skill complementarity effect to that of the time trend, we decompose the change in the skill-premium into two effects. The substitution effect is induced by the increased relative supply of skilled workers. The demand effect is either due to SBTC in unobservable variables in the KM model or to SBTC via the

of capital equipment. The regression of the US log skill-premium with on the one hand a time trend model and on the other hand the log price of capital equipment. The $R^2_{adj}$ associated to the time trend model is 0.90 and larger than that of the regression with the price of capital, i.e. 0.86. Based on the $R^2$ adjusted statistics, the KM model should be preferred to the KORV model. However, we argue that this way of testing hypotheses is biased against the capital-skill complementarity hypothesis, since the time variable picks up the effects of all unobserved variables linearly correlated with time (capital included). To show this, we generated a skill-premium series (28 observations) by $\bar{\pi}_t = 1 + 2\ln(L_{st}/L_{mt}) + 3\ln K_t + \epsilon_t$, where $\epsilon_t \sim NID(0, 1)$ and regressed this skill-premium series once with capital (the true model) and once with time trend instead. We then calculated the Error Sum of Squares of both regressions and compared the results. We found that for 2995 out of 10000 replications, the $ESS$ of the capital model exceeds that of the time trend model. This means that with a probability of 30%, we reject the capital-skill complementarity hypothesis in favour of the alternative hypothesis of unobserved SBTC when the true hypothesis is capital-skill complementarity. We also ran 10000 replications of the reverse test (true hypothesis is time trend: the skill-premium is generated with time trend) and in none of these replications were the $ESS$ associated with the capital regression lower than the $ESS$ associated with the time trend.

Robustness checks

Is capital irrelevant? The capital-skill complementarity explanation is often rejected in the literature (Acemoglu, 2002) because of its apparent lower explanatory power. Acemoglu (2002) for instance, regresses the US log skill-premium with on the one hand a time trend and on the other hand the log price of capital equipment. The $R^2_{adj}$ associated to the time trend model is 0.90 and larger than that of the regression with the price of capital, i.e. 0.86. Based on the $R^2$ adjusted statistics, the KM model should be preferred to the KORV model. However, we argue that this way of testing hypotheses is biased against the capital-skill complementarity hypothesis, since the time variable picks up the effects of all unobserved variables linearly correlated with time (capital included). To show this, we generated a skill-premium series (28 observations) by $\bar{\pi}_t = 1 + 2\ln(L_{st}/L_{mt}) + 3\ln K_t + \epsilon_t$, where

*Note:* The contributions are expressed in annual percentage rates.

capital-skill complementarity in production in the KORV model. We split the period into two sub-periods. The period 1969 to 1981 is characterized by an annual growth in capital equipment of 6.7% and the period 1981 to 1996 is characterized by a slower growth of capital equipment, annual rate of 5.7%. The demand and substitution contributions, expressed in annual percentage rates, are reported in Table 2. In the KM model, demand shifts contribute to increase the skill-premium by 2% per year. In the KORV model, demand shifts contribute to increase the skill-premium by 1.83% per year. Since in the KM model, the time trend captures the effect of all variables that are highly linearly correlated with time and omitted in the KM model, it also includes the effects of capital equipment. Therefore, we can conclude that between 1969 and 1996, 92% of the demand shifts, 1.83/2 = 0.915 in Table 2, are induced by the growth of equipment stock, although the importance of unobserved sources tend to be larger in the last period, 15% between 1981 and 1996 (1.69/2 = 0.845), than in the beginning period, 0.5% between 1969 and 1981 (1.99/2 = 0.995).

Robustness of the parameters. The Durbin–Watson statistics, reported in Table 1, indicate a possible spurious relationship in the equations of the model. The augmented Dickey–Fuller statistics indicate that the log skill-premium series and log equipment stock are not stationary, integrated of order 1 (ADF($\pi_t$) = -0.57 and ADF($\ln K_t$) = -1.65) whereas the possibility that the log skill supply series are stationary can not be rejected at 5% (ADF($\ln (L_{st}/L_{mt})$) = -3.41). We therefore regressed Equations 7 and 8 in first differences to investigate the sensitivity of the long-run model estimates. The estimates of the skill-premium equation are reported in Table 3. The estimated parameters are of relatively similar magnitude in levels and first differences and the parameters remain significant when estimated with first differences. The results are reassuring regarding the findings presented in this article.

Different capital series. We check the robustness of our results with respect to the choice of the capital variable by replacing the equipment capital by two other measures of capital, namely the stock of computers and the stock of machines. These two measures of capital grow at very different rates during the period 1969 to 1996, as can be seen from
Fig. 3. The computers stock series increases sharply in the period 1969 to 1979, annual rate of nearly 26% per year and slows down through 1996 to a yearly rate of 8.9%. In contrast, the machines stock increases relatively constantly in the period 1969 to 1996 at a moderate annual rate of 5.2%.

We replicate the analysis ran for capital equipment but for computers and machines stock instead. The results of the levels and first-differences estimations of Equation 8 with computers and machines instead of capital equipment are reported in Table 4. The percentage explained of the variance in the skill-premium is insensitive to the type of capital considered as indicated by the various \( R^2_{adj} \) statistics (i.e. 0.96 for equipment, 0.95 for machines and 0.94 for computers).

**Fig. 3.** Time-series of equipment stock, computers stock and machines stock in the Netherlands (1969–1996)

Will the skill-premium in the Netherlands rise in the next decades?

Forecasts of the Dutch skill-premium in 2020

We make use of the supply forecasts for skilled and unskilled workers provided by CBS and CPB.
The CPB (2004) forecasts a moderate growth in the stock of capital of 1.6% per year through 2020. In this article, we extrapolate this forecasts to 2020. Note that this scenario is realistic at sight of the recent decrease in firms’ investments, observed in the Netherlands, −12% between 2000 and 2004.

The data provides an estimation of the number of persons employable in the labour force from 2000 to 2020. The forecasts for the period 1997 to 2000 are obtained by linear extrapolation of the series.

We make predictions of the relative wage of skilled workers using deterministic scenarios of the growth of capital stock. The four deterministic scenarios considered are:

(i) The stock of capital grows at an annual rate of 10% during the period 1997 to 2020, corresponding to the highest historical growth rate in five consecutive years (1982–1986) between 1969 and 1996.
(ii) The stock of capital grows at 6% per year, corresponding to the average rate during the period 1969 to 1996.
(iii) The stock of capital grows at 3% per year, corresponding to the growth rate observed in the last 5 years, 1992–1996.
(iv) As predicted by the CPB Netherlands Bureau for Economic Policy Analysis, the stock of capital rises at an annual rate of 1.6% through 2020.8

The decomposition of the skill-premium forecasts under the different models and scenarios is reported in Table 5.

Using the KM model, we predict that the skill-premium will rise at an annual rate of 1.3% so that by 2020, the skill-premium will be 30% above its 1996 level (Jacobs, 2004). To meet this result with the KORV model, that is accounting for the capital-skill complementarity in production, the stock of capital would have to rise continuously until 2020 at an annual rate of 6.8%. This implied annual growth rate in the stock of capital is twice the annual rate observed in the last 5 years of our sample 1992–1996 and lies 0.8% points above the average rate in the span 1969–1996.

The increase in the skill-premium, as predicted by the KORV model, varies from 50% when capital stock rises 10% per year to −5% when the stock of capital grows at 1.6% per year through 2020.

Note: The contributions are expressed in annual percentage rates.

8 The CPB (2004) forecasts a moderate growth in the stock of capital of 1.6% per year through 2010. In this article, we extrapolate this forecasts to 2020. Note that this scenario is realistic at sight of the recent decrease in firms’ investments, observed in the Netherlands, −12% between 2000 and 2004.
V. Conclusion

The answer to the question: is the race between schooling and technology, e.g. Tinbergen (1975) lost by schooling? is empirically blurred. Economists that support the idea that shifts in the demand for skilled labour result from skill-biased technological change in unobservable variables would answer positively (30% increase in the skill-premium by 2020). In contrast, the answer of economists in favour of the capital-skill complementarity in production will depend on their expectations regarding the evolution of the price of capital. If the price of capital keeps falling at a pace comparable to that of the last decades, by 2020 the race would be lost by schooling. However, if the price of capital decreases at the same pace it did in the 90s, the skill-premium will stabilize.

Acknowledgments

I would like to thank Lex Borghans, Frank Cövers, Bart Golsteyn, Ben Kriechel, Philip Marey, Christophe Meng, Catherine Morrison Paul, Inge Sieben, Wendy Smits and Bas ter Weel for helpful comments on earlier drafts.
