Abstract
Summary background data: Hepatic sinusoidal dilatation (SD) is a histopathological entity that occurs in up to 75% of patients undergoing oxaliplatin-based chemotherapy for colorectal liver metastases (CRLM). Objective: To study the influence of SD on outcome after partial hepatectomy in patients with CRLM. Methods: Medline, Embase, CENTRAL, LILACS and CINAHL were searched for studies published between 01.01.2004 and 09.06.2015 with keywords: “sinusoidal obstruction syndrome”, “hepatic veno-occlusive disease”, and “Stuart-Bras syndrome”. Studies comprising adults who underwent partial hepatectomy for CRLM with grading of SD and registration of postoperative morbidity and/or mortality were included. Risk of bias and quality of studies were evaluated with the Quality In Prognosis Studies Instrument (QUIPS) and modified GRADE framework. Results: Search strategies produced 2007 hits from which 23 and 13 articles were extracted for qualitative and quantitative analyses, respectively. Meta-analysis on the influence of SD grade 2–3 vs. SD grade 0–1 on postoperative overall morbidity showed an odds ratio (OR) of 1.26 [95% CI 0.74, 2.12] (p = 0.40), an OR of 1.03 [0.15, 6.99] (p = 0.98) for liver failure, an OR of 1.21 [0.23, 6.35] (p = 0.82) for overall mortality, and an OR of 3.52 [0.31, 39.91] (p = 0.31) for liver-related morbidity. QUIPS showed a low to high risk of bias for studies, and GRADE showed very low quality of evidence per outcome. Conclusions: No significant effect of SD grade 2–3 on short-term outcome after partial hepatectomy was found. However, the data on which this conclusion was based were not very robust and therefore no solid conclusions could be drawn.

1. Introduction

Sinusoidal dilatation (SD) is a common manifestation of hepatotoxicity that occurs in patients with colorectal liver metastases (CRLM) after administration of oxaliplatin-based chemotherapy [1–3]. Regimens based on the platinum containing agent oxaliplatin are used extensively as neo-adjuvant therapy to downsize initially irresectable CRLM, with convincing response rates and survival outcomes [4–6]. However, liver injury is demonstrated in over 75% of patients [1,3].

SD is part of a broad range of liver injuries due to specific drugs,
in conjunction with sinusoidal obstruction syndrome (SOS). SOS is macroscopically identified as ‘blue liver’ and microscopically characterized by injury of the sinusoidal endothelial cells (SECs), parenchymal lesions (e.g. SD and peliosis), venular lesions, and fibrosis. Various pathogenic factors have been described to contribute to these histopathological changes [7]. Key features of oxaliplatin-induced toxicity are its reaction with reduced glutathione and F-actin depolymerization, which results in rounding up and subsequent dehiscence of SECs and obstruction of sinusoidal blood flow leading to SD and erythrocyte extravasation [1,8–12]. Activation of hepatic stellate cells (HSC) results in neodisposition of collagen bundles in the perisinusoidal space which, in combination with subendothelial fibroblast activation in the terminal hepatic vein, leads to fibrotic venular occlusion. In the last stage of SOS, dense perivenular fibrosis is observed and hepatic vein lumen may no longer be identified [13].

The grading system of Rubbia-Brandt et al. classifies all histological features of SOS including SD, and is routinely used for stipulating severity [1,2]. In most studies, SD functions as the standard for liver damage. Reversibility of sinusoidal injury is discussed widely, and although human and animal models show ceasing of pathological features at repeated hepatic resection [2,14], other studies show persistence or progression of lesions even after cessation of chemotherapy [15].

Clinical importance of SD is reflected in the development of hepatomegaly, ascites, splenomegaly, thrombocytopenia, portal hypertension, and systemic elevation of liver enzymes [16–19]. With regard to liver surgery, a diminished preoperative functional reserve, (transient) postoperative liver failure, higher morbidity rates and longer hospital stay, as well as impairment of postoperative liver regeneration have been reported [20,21]. Numerous studies have shown a negative influence of SD on postoperative outcome [20,22,23], yet others could not reproduce this [24–29]. This systematic review with meta-analysis aimed to determine the influence of SD on short-term outcome after partial hepatectomy in patients with CRLM.

2. Methods

2.1. Criteria for considering studies for this review

An extensive study protocol can be found in Appendix 1 (Supplementary data). This review was conducted and reported in compliance with the PRISMA and MOOSE guidelines, and followed the Cochrane protocol for prognostic factor reviews [30–32]. Studies were considered eligible for inclusion in this review when they met the following criteria: (I) studies comprising adults (≥18 years old) with CRLM, (II) who underwent major or minor partial hepatectomy, (III) with postoperative histological grading of SD in liver tissue distant from the tumour according to the scoring system of Rubbia-Brandt, (IV) and with registration of overall morbidity, liver-related morbidity, liver failure, or overall mortality (≤90 days or in-hospital) after liver resection. Case reports, comments/editions, published abstracts, and reviews were rejected, in addition to records not covering the subject or including non-adults (<18 years old). Cohort studies including patients who underwent liver surgery for malignancies other than CRLM were included albeit that this group comprised less than 30% of the total study population. No distinction was made between first and repeated resections, and studies with patients who underwent preoperative portal vein embolization (PVE) were allowed for inclusion since an effect of PVE on outcome in patients with SD was observed in a single study only [33].

2.2. Search methods for identification of studies

Search strategies in international databases Medline, Embase, Cochrane Central Register of Controlled Trials (CENTRAL), Latin American and Caribbean Health Sciences Literature (LILACS) and Cumulative Index to Nursing and Allied Health Literature (CINAHL) were performed between 01.01.2004 and 09.06.2015 using the following keywords (adjusted to the relevant database and including synonyms): “sinusoidal obstruction syndrome”, “hepatic veno-occlusive disease”, and “Stuart-Bras syndrome”. Publication date of the search strategy was set from January 2004 onwards because the widely used criterion for scoring SD from Rubbia-Brandt et al. was developed in this year [1]. The Embase strategy was independently peer reviewed by a second information specialist using the Canadian Agency for Drugs and Technologies in Health (CADTH) checklist [34]. No language restrictions or other limitations were applied. Details of the search strategy can be found in Appendix 2.

2.3. Data collection and analysis

Records were downloaded in EndNote® X7 and duplicates were automatically and manually removed. All abstracts were screened by two independent reviewers (KvM, JZ), and in the rare case of no consensus the abstract was considered for full-text scanning. One of the reviewers (KvM) screened citations of all full-text articles for additional records on the base of title or abstract. Previous research from the authors on this topic resulted in an extensive own library which was also checked for references. Records considered for full-text assessment were screened independently by two reviewers (KvM, JZ). Full-text articles were screened for inclusion in qualitative analysis and/or quantitative analysis. Articles without postoperative mortality in the study population were described qualitatively due to lack of contribution to quantitative analysis.

2.4. Data extraction and definitions

Data extraction was performed independently by two reviewers (KvM, JZ) using a data extraction form in Excel specifically created for this study. Any dissimilarity in data was discussed and solved by consensus. Inter-observer agreement was calculated with Cohen’s kappa coefficient. All information on study design and characteristics, main outcomes and possible overlap in cohort data was recorded. SD was defined according to the grading system of Rubbia-Brandt et al. [2]. In short; SD 0: absence of signs of SD; 1: mild SD (centrilobular involvement limited to one-third of the lobular area); 2: moderate SD (centrilobular involvement extending in two-thirds of the lobular area) and 3: severe SD (complete lobular involvement or centrilobular involvement extending to adjacent lobules with bridging congestion). In all analyses, ‘SD’ was defined as the presence of grade 2 or 3 SD whilst ‘no SD’ was defined as grade 0 or 1. We considered SD grade 2–3 clinically more relevant than grade 0–1, since rupture of sinusoidal wall integrity is present in grade 2 and higher. Major liver resections were defined as resection of ≥3 Couinaud segments. All outcomes were measured between 30 and 90 days after partial hepatectomy or during initial hospital admission (‘in-hospital’). Primary outcomes were overall morbidity, liver failure, and overall mortality after liver resection. Secondary outcome was liver-related morbidity after partial hepatectomy. Overall morbidity was defined as any complication (i.e. surgical and medical, excluding death) after liver resection, irrespective of severity [35]. Mortality was defined as death due to any cause after liver resection. Since consensus on the definition of liver failure is lacking [36–38], definitions were specified in the Results Section. Liver-related morbidity was...
defined as any liver-related complication (e.g. bile leakage, liver abscess, liver failure) occurring after partial hepatectomy, regardless of severity [39].

2.5. Quality assessment

Risk of bias of individual studies was determined using the Quality In Prognosis Studies (QUIPS) Risk of Bias Assessment Instrument for Prognostic Factor Studies [40,41]. The QUIPS instrument is a checklist composed of the domains study participation, study attrition, prognostic factor measurement, outcome measurement, study confounding, and statistical analysis and reporting, and produces an estimation of the risk of bias with help of a rating (high, moderate or low risk) per domain. The following definitions were chosen by the authors for rating the overall risk of bias: ‘overall low risk of bias’ was <2 domains rated as moderate risk and the remaining domains as low, ‘overall moderate risk of bias’ was ≥3 domains rated as moderate risk and the remaining domains as low, ‘overall high risk of bias’ was ≥1 domain rated as high risk, independent of the rating of the remaining domains. The quality of evidence per primary or secondary outcome was evaluated using the modified Grading of Recommendations Assessment, Development and Evaluation (GRADE) framework for prognosis studies [30,42], which is composed of eight scoring fields and aims to give an objective scoring of quality of evidence per outcome specific for the hypothesis of the user. Its fixed scoring parameters and rationale for downgrading described in the Summary of Findings Table makes GRADE the most transparent and reproducible method currently available. The starting score is based on the study design and quality can be downgraded (and in specific cases upgraded) per field. Quality of evidence is defined as (I) high quality: the true effect lies close to the estimate of the effect, (II) moderate quality: the true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different, (III) low quality: the true effect may be substantially different from the estimate of the effect or (IV) very low quality: the true effect is likely to be substantially different from the estimate of effect [30].

2.6. Data handling and statistical methods

Meta-analyses of two or more studies per outcome were performed in Review Manager 5.3 and depicted in forest plots. The principal effect measures consisted of a pooled odds ratio (OR) with 95% confidence intervals (95% CI) calculated by the Mantel-Haenszel test for dichotomous outcomes, which was chosen because of low event rates and small sample sizes. A p-value <0.05 was considered significant. A random effects model was chosen instead of fixed effects because the true effect size was expected to vary between different studies. Statistical heterogeneity was evaluated with the X^2 test, I², and comparison of point estimates between studies and overlap of 95% confidence intervals. Clinical heterogeneity was investigated by comparing different patient populations (SD 2–3 vs. SD 0–1; SD 1–3 vs. SD 0) and different extents of liver resection (all resections vs. major resections only). In case of significant heterogeneity, defined as an I² > 50% and a X^2 test p-value of <0.10 (considered significant due to a potentially low number of included studies in meta-analyses), the OR and 95% CI were omitted from the forest plot.

3. Results

3.1. Search results

The conducted search resulted in a total of 2777 hits. Fig. 1 shows the selection process of included studies in detail. After duplicate removal, 2007 hits remained. A total of 50 full-text articles were assessed for eligibility. Four more records were selected for full-text article scanning during reference checking, and another four potentially relevant records were selected from the own library. After application of the predefined inclusion and exclusion criteria on the total of 58 full-text articles by the two reviewers (KVM, JZ), 23 articles were included in qualitative synthesis. Inter-observer agreement kappa was 0.81 and dissimilarity was solved by discussion. Of the included studies for qualitative analysis, 13 studies contained data for quantitative analysis. Study and patient characteristics, main outcomes and main conclusions of the studies are summarized in Table 1.

3.2. Included studies

A total of eight studies could be included in quantitative analysis to estimate the effect of SD grade 2–3 vs. SD grade 0–1 on postoperative outcomes after partial hepatectomy. All studies but two were retrospective cohort studies which enrolled at least 50 patients [22,56]. Each study was published in an international, peer-reviewed journal between 2006 and 2013. Postoperative morbidity could be evaluated in two studies comprising a total of 248 patients [26,44], and in two studies encompassing a total of 319 patients, postoperative liver failure was studied [47,56]. Three studies investigated postoperative mortality in a total of 702 patients [21,55,56], and postoperative liver-related morbidity was evaluated in two studies with a total of 147 patients [22,26]. For each of above outcomes, a single study addressed the effect of SD in patients undergoing major liver resection [26,53].

3.3. Patient characteristics

All cohort studies included patients who underwent minor or major hepatectomy and of whom liver quality was assessed postoperatively according to the grading system of Rubbia-Brantd [1]. In total 63% of patients who underwent surgery were male, and median age was 61 years [range: 18 to 89]. CRLM was the indication for liver surgery in all patients.

3.4. Primary outcomes

3.4.1. Postoperative morbidity

A meta-analysis on the influence of SD grade 2–3 vs. SD grade 0–1 on postoperative morbidity was conducted and depicted in Fig. 2A. The overall effect of SD vs. no SD on postoperative morbidity showed a p-value of 0.40 with an OR of 1.26 [95% CI 0.74–2.15]. Tests evaluating consistency of results showed an I^2 of 0% and a X^2 test p-value of 0.74. Although the use of random effects was deliberately chosen, testing with fixed effects did not have influence on the results (OR 1.26 [95% CI 0.73–2.15], p = 0.40). SD was no risk factor for morbidity in studies where original data was not provided for quantitative analysis [21,24,50,55].

In patients undergoing major hepatectomy (n = 59, hemi-hepatectomy or extended hemihepatectomy), 17 of 29 patients (59%) with SD developed morbidity vs. 19 out of 30 patients (63%) in patients without SD (not depicted in forest plot) [26].

3.4.2. Postoperative liver failure

The effect of SD on postoperative liver failure (PLF) could be tested in two studies (Fig. 2B). In the study of Kishi et al., liver failure was defined as peak total bilirubin value > 120 μmol/L in the postoperative course [47], while Vigano et al. applied serum bilirubin >50 μmol/L and/or prothrombin time <50% on or after postoperative day (POD) 5 [56]. An OR of 1.03 [95% CI 0.15–6.89]
was found with a p-value of 0.98 for SD. Significant heterogeneity between studies was reflected in an $I^2$ of 65% and p-value of $X^2$ test of 0.09, and overlap in 95% CI was barely present. Totals were subsequently omitted from the forest plot. One qualitative study showed no PLF in both the patients with or without SD [23].

The study of Soubrane et al. was the only study that looked at postoperative liver failure in major resections only, and defined liver failure as a serum bilirubin $>50 \mu$mol/L and prothrombin time $<50\%$ on POD5 [53]. Liver failure occurred in eight of 38 patients with SD vs. zero in 13 patients without SD (not depicted in forest plot).

### 3.4.3. Postoperative mortality

Three studies were available for examining the influence of SD...

RCoHS: retrospective cohort study; PCoHS: prospective cohort study; Quan: quantitative and qualitative data; Qual: solely qualitative data; CALI: chemotherapy-associated liver injury; Ctx: chemotherapy; APRI: aspartate transaminase to platelet ratio index; ox-based: oxaliplatin-based; cetu: cetuximab; bev: bevacizumab; SVI: splenic volume increase; SOS: sinusoidal obstruction syndrome; SD: sinusoidal dilatation; SI: sinusoidal injury; mod: moderate.

a Considerable overlap between patient cohorts was confirmed by the authors. Larger sample size and broader inclusion criteria contributed to the decision to solely include Narita (2012) in quantitative analysis.

b Considerable overlap between patient cohorts was confirmed by the authors. Larger sample size and broader inclusion criteria contributed to the decision to solely include Pessaux (2010, n=72) in qualitative analysis.

The rate of liver dysfunction is high among patients with moderate to severe CALIs. No association is found between oxaliplatin use and SD or SI and postoperative morbidity.

3.5. Secondary outcome

3.5.1. Liver-related morbidity

Two studies were available for estimating the influence of SD on postoperative liver-related morbidity (Fig. 2D). The study of Gomez-Ramirez et al. included the following complications: biliary fistula, haemorrhage, abscesses, uninfected collections and liver failure [22], while Makowiec et al. included hepatic insufficiency, biloma and/or symptomatic ascites requiring interventional or medical treatment [26]. An OR of 3.52 [95% CI 0.31–39.91] was not significant.

Fig. 2. Postoperative short-term outcomes sd grade 2–3 vs. sd grade 0–1. Meta-analyses on the influence of sinusoidal dilatation (SD) grade 2–3 versus SD grade 0–1 on the complication rate after partial hepatectomy for colorectal liver metastases. A. Postoperative overall morbidity. Meta-analysis on the influence of sinusoidal dilatation (SD) grade 2–3 versus SD grade 0–1 on the morbidity rate due to any cause after partial hepatectomy for colorectal liver metastases. B. Postoperative liver failure. Meta-analysis on the influence of sinusoidal dilatation (SD) grade 2–3 versus SD grade 0–1 on the liver failure rate after partial hepatectomy for colorectal liver metastases. C. Postoperative overall mortality. Meta-analysis on the influence of sinusoidal dilatation (SD) grade 2–3 versus SD grade 0–1 on the mortality rate due to any cause after partial hepatectomy for colorectal liver metastases. D. Postoperative liver-related morbidity. Meta-analysis on the influence of sinusoidal dilatation (SD) grade 2–3 versus SD grade 0–1 on the liver-related morbidity rate after partial hepatectomy for colorectal liver metastases. SD: sinusoidal dilatation, M-H: Mantel-Haenszel, Random: random effects model, 95% CI: 95% confidence interval.
found with a p-value of 0.31 for SD. $I^2$ was 83% with a p-value of $X^2$ test of 0.01. Overlapping of intervals between included studies was barely present; hence totals were omitted from the forest plot. In major hepatectomy only, eight out of 30 patients without SD vs. 10 out of 29 patients with SD developed liver-related complications [26].

### 3.6. Sub group analysis

Five studies compared SD grade 1–3 with SD grade 0. Analyses on these subgroups were performed and resulting forest plots are presented in Appendix 3. In summary, the effect of SD grade 1–3 on the primary outcome postoperative morbidity could be tested in three studies (n = 577) [20,54,57], liver failure in one study (n = 90) [20], and mortality in two studies (n = 433) [50,57]. Again, the risk for postoperative overall morbidity after minor or major liver resection in the SD group tended to be higher (OR 1.53, 95% CI 0.96–2.44, $p = 0.08$) than in the group without SD (Appendix 3A).

There was limited evidence of effect (one study) of SD on PLF, and therefore no meta-analysis was conducted on this outcome. This study showed a higher incidence of PLF, which was defined as a serum bilirubin $>50$ $\mu$mol/L and a prothrombin time $<50$% on POD5 or thereafter, in the SD group (three out of 38 patients with SD vs. zero out of 52 patients without SD) [20]. Estimate points of effect for postoperative mortality resulted in an OR of 0.51 and p-value of 0.96 (Appendix 3B). Statistical heterogeneity analysis revealed $I^2 = 0\%$ and p-values of 0.77 and 0.40 for postoperative overall morbidity and mortality, respectively. No mortality was observed in patient groups with and without SD in two studies [20,54]. Secondary outcome measure liver-related morbidity could be tested in two studies [20,57] and yielded an OR of 2.22 (95% CI 0.34–14.32, $p = 0.40$) and an $I^2$ of 64% ($p = 0.10$) (Appendix 3C).

For major resections only, forest plots were constructed for postoperative overall morbidity and liver failure (Appendix 4). Two studies that included a total of 137 patients were available for a meta-analysis on postoperative morbidity (Appendix 4A) [20,49]. An OR of 2.00 [95% CI 0.12–33.34] with a p-value of 0.63 for SD were found. $I^2$ was 83% with a p-value of $X^2$ test of 0.02, and totals were omitted from the forest plot. The same two studies were available for a meta-analysis on postoperative liver failure (Appendix 4B). Whereas Nakano et al. defined postoperative liver failure as a serum bilirubin $>50$ $\mu$mol/L and a prothrombin time $<50$% on or after POD5 [20], Narita et al. defined this as a serum bilirubin $>50$ $\mu$mol/L and a prothrombin time $<50$% on POD5 and/or a postoperative serum bilirubin $>120$ $\mu$mol/L [49]. An OR of 2.67 [95% CI 0.94–7.53] with a near-significant p-value of 0.06 for SD was found. No heterogeneity was detected as reflected in an $I^2$ of 0% with a $X^2$ test p-value of 0.73. No mortality in patients with or without SD was observed in two studies on major hepatectomy [20,46]. Liver-related morbidity was seen in the study of Nakano et al. [20], with three patients showing liver-related morbidity in the patient group with SD (n = 20) versus one patient in the patient group without SD (n = 16).

### 3.7. Quality of the included studies

#### 3.7.1. Risk of bias assessment

Risk of bias was assessed using the modified QUIPS checklist [40,41] and overall ratings are depicted in Table 1. Thirteen articles showed an overall low risk of bias, two studies showed moderate risk of bias and ten articles were appraised as having a high risk of bias. The assessment of risk of bias per domain and sub domain for individual studies can be found in Appendix 5.

#### 3.7.2. GRADE assessment

Study findings were assessed with the modified GRADE checklist [42,58] and are shown in the Summary of Findings Table (Table 2). Footnotes provide detailed information about the rationale for downgrading. In short, evidence for all outcomes was rated as very low. Each outcome was downgraded on the base of study design (phase 1 explanatory studies). Other reasons for downgrading were indirectness in definition or time period of outcome measures and imprecision in data as shown by forest plots. Only QUIPS domain 1 to 4 were taken into account for downgrading, since domains 5 and 6 assess quality of the statistical analysis which did not influence quality of the current meta-analysis because we extracted only raw data from the manuscripts. A detailed rating per domain can be found in Appendix 6. A Summary of Findings Table for outcomes on SD grade 1–3 vs. 0 and a detailed rating per domain can be found in Appendix 7 and 8.

### 4. Discussion

The present study found no significant influence of moderate to severe SD (grade 2–3) in comparison to no or mild SD (grade 0–1) on outcome after partial hepatectomy. Likewise, no influence on postoperative outcome was apparent when comparing mild in severe SD (grade 1–3) to no SD (grade 0). After data extraction, all studies were subjected to assessment with the QUIPS and GRADE tools to grade the quality of included evidence, strength of recommendations and risk of bias. Critical evaluation subsequently showed a low to high risk of bias for individual studies and very low quality of outcome-specific evidence, thereby leading to limited confidence in the provided evidence with regards to our hypothesis. An important explanation for less trust in the provided evidence is the study design of included articles. All but one study consisted of explanatory phase 1 studies, which are performed in early phases of investigation to generate a hypothesis and are considered weaker evidence than studies which confirm the independent effect of a specific prognostic factor on outcome (phase 2 studies), or studies that explore the underlying mechanism for prognosis of certain diseases (phase 3 studies) [30,59]. Moreover, variation in inclusion criteria, sample size, wide confidence intervals crossing the null value, and different definitions of outcomes, were factors that negatively affected the quality of the evidence specified for our hypothesis. In light of these findings, no solid conclusions can be drawn and this study cannot provide clinical advice on the topic.

Some studies showed contrasting data, which may be partially explained by different inclusion criteria. While patients who received bevacizumab were intentionally excluded in some studies [26,50], other studies did allow inclusion of these patients [22,47]. Bevacizumab, an angiogenesis inhibitor that inhibits tumour growth by binding to vascular endothelial growth factor, is often co-administered in oxaliplatin-based chemotherapy regimens for patients with CRML [60]. Apart from the ongoing discussion about the potential benefit of prevention or reversibility of histological injury [2,61], bevacizumab itself may induce relevant toxic side effects which can affect recovery after partial liver resection [62–64]. Moreover, it is usually advised to end chemotherapy, particularly when bevacizumab is co-administered, at least five weeks before liver surgery [65]. Studies included in this systematic review report a range from 2 to 9 weeks for the interval between the last cycle of chemotherapy and surgery. It is currently unclear whether pathological characteristics of SOS are reversible, if a lower grade of SOS is linked to a higher likelihood of reversibility, and in which time frame this would occur. Patients with a long time interval between chemotherapy cessation and surgery were observed to have less SD compared to a short time interval [20], whereas irreversibility of SOS and even deterioration in time have been
described by Mentha et al. [15].

Likewise, a link between the number of administered cycles of chemotherapy and grade of liver injury is uncertain, and the median number of administered cycles in this meta-analysis ranged from 6 to 12. Whereas Karoui et al. found that the morbidity rate was correlated with the number of chemotherapy cycles [46], this correlation was not confirmed by Van Der Pool et al. who compared patients who received less than six cycles with those who received six or more cycles [54]. One could speculate that patients with longer duration of chemotherapy may have had more extensive disease and therefore more complex surgical interventions. Almost all studies corrected for the extent of liver resection, but extrahepatic procedures and vascular reconstructions were not taken into account in more than half of studies. The impact of these procedures on outcome can be substantial [66,67].

In patients with a critical future liver remnant due to anticipated extensive surgery, portal vein embolization (PVE) is the preferred procedure to induce preoperative enlargement of the future liver remnant [68]. The effect of SD on liver regeneration after PVE has been investigated in one study, in which PVE had a negative effect on postoperative liver regeneration [33]. Moreover, post-PVE histopathological changes in a previous report were the rationale for Vauthey et al. [55] and Brouquet et al. [44] to exclude these patients from their cohorts [69]. This resulted in a less complete reflection of the general surgical population. However, inclusion of these patients may have an impact on postoperative outcomes either by a diminished hypertrophic response or because this group of patients often undergoes extended hepatectomies and is already at higher risk.

With regard to variations in definitions, outcome after liver resection was expressed in numerous terms and time frames. Mortality was assessed within 30, 60, or 90 days after surgery or during hospital admission, and morbidity was described as overall, medical, surgical, liver-related or infectious, with no consensus on employed definitions. This underscores the necessity of a uniform outcome set after liver surgery in order to ensure clear and consistent clinically relevant data, and to allow comparison between future trials and cohort studies in meta-analyses [39].

On the basis of stated differences in inclusion criteria and outcome, which all might have influenced the outcome after liver resection to an unknown extent, ideally a phase two study in which all confounders are corrected for in a statistically appropriate way should be conducted. Our group recently initiated such a study in the form of an individual patient data meta-analysis [70].

5. Conclusion

This study aimed to evaluate the influence of moderate to severe SD on outcome in patients undergoing partial hepatectomy for CRLM. Although many individual studies suggest a negative impact on postoperative (liver-related) morbidity, liver failure and mortality, the present meta-analysis could not confirm this data. However, trust in the obtained evidence was low and therefore no solid conclusions can be drawn. This study emphasizes the importance of critical risk of bias assessment and evaluation of quality in meta-analyses, to provide the most robust level of evidence for clinical decision making. It also highlights the need for unambiguous definitions of outcome in surgical oncology.
