Abstract

Purpose: Genome-wide DNA methylation analyses have identified hundreds of candidate DNA-hypermethylated genes in cancer. Comprehensive functional analyses provide an understanding of the biologic significance of this vast amount of DNA methylation data that may allow the determination of key epigenetic events associated with tumorigenesis.

Experimental Design: To study mechanisms of cysteine dioxygenase type 1 (CDO1) inactivation and its functional significance in breast cancer in a comprehensive manner, we screened for DNA methylation and gene mutations in primary breast cancers and analyzed growth, survival, and reactive oxygen species (ROS) production in breast cancer cells with restored CDO1 function in the context of anthracycline treatment.

Results: DNA methylation-associated silencing of CDO1 in breast cancer is frequent (60%), cancer specific, and correlates with disease progression and outcome. CDO1 function can alternatively be silenced by repressive chromatin, and we describe protein-damaging missense mutations in 7% of tumors without DNA methylation. Restoration of CDO1 function in breast cancer cells with epigenetically silenced CDO1 resulted in restored expression and increased sensitivity to anthracyclines.

Conclusion: We report that silencing of CDO1 is a critical epigenetic event that contributes to the survival of oxidative-stressed breast cancer cells through increased detoxification of ROS and thus leads to the resistance to ROS-generating chemotherapeutics including anthracyclines. Our study shows the importance of CDO1 inactivation in breast cancer and its clinical potential as a biomarker and therapeutic target to overcome resistance to anthracyclines.

Introduction

Loss of proper tumor suppressor function leads to the initiation and progression of human cancer (1) and aberrant epigenetic alterations including DNA promoter hypermethylation can be responsible for such functional loss (2).

Cysteine dioxygenase type 1 (CDO1), recently identified as a candidate hypermethylated gene within the functional breast cancer hypermethylome (7), is a non–heme iron dioxygenase (8). CDO1 determines the flux between cysteine catabolism and glutathione synthesis (9) by catalyzing the oxidation of cysteine to cysteine sulfinic acid in the presence of molecular oxygen (10). Abnormal or deficient CDO1 activity has been implicated in a variety of neurologic and autoimmune diseases such as Parkinson’s, Alzheimer’s, rheumatoid arthritis, systemic lupus erythematosus...
Translational Relevance

Breast cancer is a heterogeneous disease driven by molecular changes of genetic and epigenetic nature. By screening for genome-wide DNA methylation changes in breast cancer, we identified cysteine dioxygenase type 1 (CDO1) as a DNA-hypermethylated gene. We show that CDO1 is frequently DNA methylated in breast primary tumors and that this event is associated with adverse clinical features and poor prognosis. On the basis of the suggested role for CDO1 in the oxidative stress response of cancer cells, we examined its role in the resistance to the reactive oxygen species (ROS)-generating chemotherapeutic class of anthracyclines. We found that restoration of CDO1 function in breast cancer cells alters the oxidative stress response in a way that it leads to the sensitization to anthracyclines. We further provide potential clinical implications for this finding by showing that priming with 5-azacytidine of breast cancer cells with epigenetically silenced CDO1 increases the sensitivity to anthracyline therapy. This finding provides a potential clinical strategy to overcome resistance to this drug and DNA methylation of CDO1 may be useful as a marker to select patients for priming with 5-azacytidine.

(11–13), and recently in carcinogenesis. CDO1 is a promising prognostic biomarker in malignancies with loss of CDO1 expression being associated with relapse of Wilms tumor (14) and DNA methylation of the CDO1 promoter is associated with poor prognosis in patients with breast cancer (7, 15). CDO1 has also been implicated in several studies to play a role in the oxidative stress response of cancer cells (16, 17).

Many cancer cells, in particular at advanced stage, function with higher basal levels of endogenous oxidative stress than normal cells. Under persistently increased reactive oxygen species (ROS) production, cancer cells adapt to such stress to escape oxidative damage and ROS-induced apoptosis by developing an enhanced, endogenous detoxification capacity (18). The mechanisms of ROS stress adaptation involve the activation of ROS-scavenging enzymes and endogenous antioxidants (19, 20) such as glutathione (21). Although increased ROS stress promotes initiation and progression of cancer (22, 23), excessive levels of ROS can be toxic (24) and lethal if exceeding a threshold above cellular tolerability (25). This concept is of therapeutic interest, because it is thought that increased ROS production makes cancer cells more vulnerable to damage by further ROS insults induced by exogenous ROS-generating agents including the chemotherapeutic class of anthracyclines (24, 26). The redox adaptation of cancer cells, however, can provide a mechanism for resistance to anthracyclines (24, 27).

We present a comprehensive study that addresses the functional significance of silencing of CDO1 during breast tumorigenesis. We report the frequent inactivation of CDO1 by multiple mechanisms (60% DNA methylation, 20% missense mutations) in breast cancer and also across multiple other types of cancer. Cells with restored CDO1 function show reduced growth, viability, and ROS detoxification capacity and increased sensitivity to anthracyclines. Given these findings, we suggest that silencing of CDO1 is a critical event that drives tumorigenesis and contributes to the survival of oxidative-stressed breast cancer cells and their resistance to anthracyclines through reducing cellular ROS levels.

Materials and Methods

Cell culture and drug treatment

Cell lines were purchased from American Type Culture Collection and cultured in appropriate media (Mediatech) supplemented with 10% FBS (Atlanta Biologicals) and 1 × Penicillin–Streptomycin (Mediatech) at 37°C in 5% CO2 atmosphere. The HCT116 derivative cell line lacking the major DNA methyltransferases DNMT1 and 3b (DNMT1−/− and DNMT3b−/−; double knockout or DKO) was maintained as previously described (28). Drug treatment with 5-aza-2′-deoxycytidine (DAC) and trichostatin A (TSA) were carried out as previously described (7). For glutathione depletion, cells were treated with 0.5 mmol/L buthionine sulfoximine (BSO). Doxorubicin was supplemented in doses ranging from 0.078 to 20 μmol/L to determine LD50 dosage and 5-azacytidine in doses ranging from 1 to 5 μmol/L, chosen for maximal CDO1 expression.

Patient samples

Primary tumor specimen and normal breast tissues from cancer-free donors were obtained from the archives of the Department of Pathology, Johns Hopkins University (Baltimore, MD) and Department of Pathology, GROW-School for Oncology and Developmental Biology, Maastricht University Medical Center (the Netherlands) with Institutional review board approval and Health Insurance Portability and Accountability Act compliance. Genome-wide methylation and expression data of primary tissues were also used from The Cancer Genome Atlas (TCGA; http://cancergenome.nih.gov/).

Gene expression, methylation analysis, and ChIP

RNA was extracted using RNeasy Mini Kit (Qiagen) or purchased from Stratagene (normal tissues). For reverse transcriptase (RT) and real-time RT-PCR, 1 μg RNA was reverse transcribed into cDNA using Ready-To-Go You-Prime First-Strands Beads (GE Healthcare) with addition of pd[N]6 Random Hexamers (GE Healthcare) according to the manufacturer’s instructions. Genomic DNA was extracted following a standard phenol–chloroform extraction and bisulfite modified using the EZ DNA Methylation Kit (Zymo Research). Methylation-specific PCR (MSP) was conducted as previously described (29). PCR products for bisulfite sequencing were cloned using the TOPO TA Cloning Kit (Invitrogen), purified from single colonies using QIAprep Spin Miniprep Kit (Qiagen), and sequenced with...
M13 reverse primer by Johns Hopkins Medical Institutions Synthesis & Sequencing Facility. For chromatin immunoprecipitation (ChIP), cells were crosslinked in 1% formaldehyde as previously described (30). Nuclear extraction using CEBN and CEB (cytoplasmic extraction buffer), and ChIP on ~1 × 10⁶ cells per IP was conducted as previously described (31). α-H3-K4me2 and α-H3-K27me3 antibodies from Millipore were used. IP-specific products were amplified using real-time PCR.

**Mutation analysis**

CDO1 coding exons were amplified and purified PCR products were bidirectionally sequenced using DNA Sequencing Kit BigDye-Terminator Cycle Sequencing Ready Reaction (Applied Biosystems). Sequencing products were separated with the Applied Biosystems ABI3730 Sequencing System and analyzed with Lasergene software (DNASTAR). Protein damaging scores for identified mutations were calculated using PolyPhen-2 software at: http://genetics.bwh.harvard.edu/pph2/.

**Immunohistochemistry**

CDO1 protein expression was detected on the sections of formalin-fixed and paraffin-embedded breast tissue (normal and tumors) using Vectastain blocking serum (Vector Laboratories), α-CDO1 primary antibody (Abcam), α-rabbit biotinylated secondary antibody (Vector Laboratories), horseradish peroxidase–labeled Vectastain Elite ABC Rabbit IgG Kit (Vector Laboratories), and 3,3′-diaminobenzidine (Sigma) as substrate. All slides were counterstained with DAKO hematoxylin and Scotts Blue.

**Expression vectors**

Wild-type CDO1 (NM_001801.2) or mutant CDO1 (Y157F; ref. 32) was cloned into pcDNA3.1/V5-His B expression vector (Invitrogen). Tetracycline-inducible CDO1-stable cells were generated using the T-REx System (Invitrogen). Expression of CDO1 was induced with 0.5 μg/mL doxycycline.

**Western blot analysis**

CDO1 protein expression was detected in whole-cell protein extracts with either α-V5 (Invitrogen) or α-CDO1 (Abcam).

**Colony formation and soft-agar assay**

Cells, transiently transfected with CDO1, were harvested 24 hours after transfection, replated in 10 cm² dishes in triplicates and selected with 0.8 mg/mL Geneticin/G418 (Invitrogen) for 15 days. Colonies were stained with Giemsa and counted. Soft-agar assays were started 48 hours following transfection. A total of 1.5 × 10⁴ cells in complete media containing 0.4% agar were layered on top of 0.6% agar in 24-well plates in duplicates. Colonies were selected with 0.8 mg/mL Geneticin/G418 (Invitrogen) for 28 days and counted after staining with 0.005% crystal violet.

**Cell viability assay**

Cell viability was measured using CellTiter96 kit (Promega). Cells were incubated in MTS reagent for 4 hours at 37°C. Absorbance was measured at 490 nm.

**Measurement of ROS production**

ROS production was measured using CM-H2DCFDA probe (Invitrogen). Cells were loaded with 5 μmol/L CM-H2DCFDA probe in phenol red–free and serum-free media for 1 hour. Fluorescence was measured at 493 nm excitation and at 523 nm emission.

**Statistical analysis**

Tumor stage and gene methylation status were correlated using Pearson χ². HR for prognostic value of gene methylation status was calculated using univariate and multivariate Cox regression analysis. Student t test and trend test were used to conduct group comparisons for colony formation, soft-agar, ROS, and cell viability assays. Gene expression and methylation status of TCGA data were correlated calculating a Spearman correlation coefficient. P values less than 0.05 were considered significant. All statistical analyses were conducted using the STATA 9.2 software package.

**Results**

**Silencing of CDO1 is associated with DNA promoter hypermethylation or repressive chromatin structure**

CDO1 (Supplementary Fig. S1 illustrates the genomic location, structure, and CpG island of the CDO1 gene) was identified as a candidate hypermethylated gene within the functional breast cancer hypermethylome (7), where potential DNA-hypermethylated genes appear in a zone in which gene expression was not detectable in untreated cells and cells treated with the histone deacetylase inhibitor TSA (<0.5 log-fold), but increased more than 0.5 log-fold in cells treated with the DNMT inhibitor DAC. CDO1 appeared in this characteristic spike of potentially DNA-hypermethylated genes in 3 of 4 tested invasive breast cancer cell lines (3.49 log-fold in MDA-MB-231, 1.24 log-fold in MCF7, and 1.48 log-fold T-47D; Fig. 1A). Conversely, CDO1 did not appear in the spike of potentially DNA-hypermethylated genes in nontransformed human mammary epithelial cells (HMEC), suggesting that CDO1 DNA methylation occurs specifically in cancer. In HMECs, CDO1 was silenced at basal level (untreated), but reexpressed with DAC (0.73 log-fold) and TSA (0.54 log-fold; Fig. 1A).

The mRNA expression status of CDO1 was validated in untreated as well as DAC- and TSA-treated MDA-MB-231, MCF7, and T-47D breast cancer cells or HMECs (Fig. 1B). In addition, we detected CDO1 baseline transcription in normal breast tissue. Next, we examined the basal DNA methylation status of CDO1 using bisulfite sequencing. The CDO1 promoter is unmethylated in normal breast and HMECs, densely methylated in MDA-MB-231 and
MCF7 cells, and partially methylated in T-47D cells (Fig. 1C). To investigate whether the loss of \textit{CDO1} expression in HMECs could be due to histone modifications, we next conducted ChIP for histone marks at the \textit{CDO1} promoter region in HMECs, MDA-MB-231, and 293 cells. \textit{CDO1}-expressing 293 cells are enriched for the active H3K4me2 mark and have low levels of the repressive H3K27me3 mark, whereas MDA-MB-231 cells, which have \textit{CDO1} densely methylated, have low levels of the active and the repressive mark (Fig. 1D). In contrast, HMECs, which have \textit{CDO1} silenced but not methylated, display a bivalent chromatin pattern with the highest levels of the repressive H3K27me3 mark and relatively high levels of the H3K4me2 mark.

DNA methylation-associated silencing of \textit{CDO1} is cancer specific, frequent, and correlates with disease progression and outcome

We studied DNA methylation of \textit{CDO1} in 20 normal breast specimens from cancer-free patients (Supplementary Table S1A) as well as in a cohort of 185 primary breast cancers including stages 0 (ductal carcinoma in situ [DCIS]) to 4 tumors (Supplementary Table S1B). DNA methylation of \textit{CDO1} is frequent and cancer-specific, that is, DNA methylation was detected in 108 of 185 breast cancers (60%), but in none of the tested 20 normal breast samples (Fig. 2A left for selected samples). Next, we examined \textit{CDO1} protein expression by immunohistochemistry on selected tumor samples and in normal breast tissue. In normal

Figure 1. Silencing of \textit{CDO1} is associated with DNA promoter hypermethylation or repressive chromatin structure. A, appearance of \textit{CDO1} within the breast cancer hypermethylome. Cell lines were treated with either 5 \textmu{m}ol/L DAC for 96 hours or 300 nmol/L TSA for 18 hours. Gene expression changes (analyzed on 4 \times 44 K Agilent platform) are plotted by fold change (log scale) after DAC (y-axis) or TSA (x-axis) treatment. B, quantitative mRNA expression of \textit{CDO1} in DAC- (5 \textmu{m}ol/L 96 hours) or TSA- (300 nmol/L 18 hours) treated cells is shown in fold change (log2) relative to mock-treated cells. Expression of \textit{CDO1} in normal breast (NB) is shown in relation to basal expression levels of \textit{CDO1} in other cell lines. Group comparisons were carried out using Student \textit{t} test. *, \textit{P} < 0.05. C, bisulfite sequencing of the \textit{CDO1} promoter region from –192 bp to +60 bp relative to the transcription start site (TSS). White and black circles represent unmethylated and methylated CpG dinucleotides, respectively. D, ChIP at the \textit{CDO1} promoter region from –154 bp to –29 bp relative to TSS for +H3K4me2 and −H3K27me3. Data presented are the mean levels of enrichment relative to input obtained by real-time PCR from 2 independent experiments ± SEM.
breast, CDO1 is uniformly expressed in the cytoplasm of ductal termini cells (Fig. 2A right, top left). In DCIS, CDO1 expression is lost in hyperproliferative ductal termini where CDO1 is methylated but not in normal differentiated ductal termini (Fig. 2A right, top right and Fig. 2A left, sample breast cancer 013a). In higher stage breast cancers, we also observed a correlation between CDO1 expression and CDO1 methylation status. A methylated CDO1 promoter was associated with the loss of CDO1 expression, (breast cancer 060a, Fig. 2A left and 2A right, bottom left), whereas an unmethylated promoter correlated with retained expression of CDO1 (breast cancer 062a, Fig. 2A left and 2A right, bottom right). We next used data of 255 primary breast cancers from the TCGA database and determined a significant inverse correlation ($\rho = -0.47$, $P = 1.7e-15$) between DNA methylation and expression of CDO1 (Fig. 2B).

We next tested whether the presence of CDO1 methylation altered prognosis of women with breast cancer. Common prognostic clinicopathologic variables were compared with CDO1 methylation status in our cohort of 185 patients with breast cancer. The frequency of CDO1 methylation significantly increased with tumor stage, i.e., 44% in stage 0/DCIS, 53% in stage 1 and 2, and 81% in stage 3 and 4 tumors (Fig. 2C and Supplementary Table S2). In addition, CDO1 was significantly more frequently methylated in tumors with lymphovascular invasive (lvI)/perinodal invasive
assayed the expression status of in multiple cancer types (pni) breast cancers ($P = 0.011$; 52% in hpi/pni neg breast cancers and 73% in hpi/pni pos breast cancers). Furthermore, a methylated CDO1 promoter status was associated with an unfavorable patient outcome [HR 2.13, 95% confidence interval (CI) 1.17–3.86, $P = 0.013$], but not independently of age and stage (HR 1.10, 95% CI 0.57–2.12, $P = 0.771$). A survival curve based on the univariate Cox regression model is shown in Fig. 2D.

DNA methylation-associated silencing of CDO1 occurs in multiple cancer types

We expanded our efforts to analyze the DNA methylation and expression status of CDO1 in other tumor types. We assayed the CDO1 expression status in normal tissues as well as in 3 corresponding cancer cell lines (ovary, lung, pancreas, and liver). CDO1 was expressed in all tested normal tissues but not expressed in association with DNA promoter methylation in the corresponding cancer cell lines with the exception of HEPG2 liver cancer cells, in which the CDO1 promoter is unmethylated (Supplementary Fig. S2A). We further determined CDO1 methylation status in primary tumor specimens of these tumor types. We found CDO1 to be commonly methylated (>60%) in ovary, lung, and pancreas cancer (Supplementary Fig. S2B), but not in hepatocellular cancer (9%). Again, using data from the TCGA database, analysis of 104 primary lung cancers and 584 primary ovarian cancers confirmed an inverse relationship (lung cancer: $r = 0.60$, $P = 1.6e-63$ and ovarian cancer: $r = -0.62$, $P = 1.6e-63$) between DNA methylation and expression of CDO1 (Supplementary Fig. S2C). As in breast cancer, we observed a correlation between tumor stage and CDO1 methylation frequency in TCGA lung and ovarian cancers (Supplementary Fig. S2D).

Tumor-specific point mutations within the CDO1 gene have a predicted protein-damaging effect

To test whether CDO1 may be inactivated by ways other than epigenetic mechanisms, we screened for mutations within the CDO1 gene in 60 primary breast cancers (unmethylated CDO1 promoter status). We found 9 single-nucleotide polymorphism in 10 patients (17%; ref. Table 1) leading to amino acid substitutions (missense mutations). The identified mutations did not associate with an unfavorable patient outcome. To evaluate the functional significance of these mutations, the PolyPhen-2 software was used to calculate a protein damage score. Three mutations (T4I, L62F, and E79K) reached a score of approximately 1, predicting for a protein damaging effect (values near 1 are predicted to be deleterious) with the highest possible probability. The Y157F mutation was introduced as a control into this assay. This mutation, within the catalytic center of the CDO1 enzyme, has been shown to reduce the enzymatic activity to up to 95% (32). A calculated protein damaging score of 0.999 reliably predicted for the experimental proven loss-of-function caused by this mutation. Subsequently, we confirmed the 3 mutations with the highest damage scores as tumorm-specific by screening normal tissue of the 4 patients that harbored these mutations in their tumor. Supplementary Figure S3 provides chromatograms of the tumor and matching normal tissue. Overall, we identified 4 of 60 patients (7%) that harbor tumor-specific and protein-damaging point mutations within the CDO1 gene.

Restoration of CDO1 function reduces growth and viability of cancer cells and their capacity to detoxify ROS

To test whether CDO1 can alter cancer cell growth, we conducted colony formation and soft-agar assays after transient expression of CDO1 in MCF7 and MDA-MB-231 cells, in which endogenous expression of CDO1 is silenced by DNA methylation. Following expression of enzymatic active wild-type CDO1 (CDO1-WT) in MCF7 and MDA-MB-231 cells, cells formed markedly fewer colonies (Fig. 3A and Supplementary Fig. S4A and S4B) on plastic and in soft-agar than cells transfected with empty vector (pcDNA3.1) or mutant CDO1 protein (CDO1-MU). Notably, expression of enzymatic impaired CDO1-MU protein suppressed growth of cells compared with cells expressing empty vector, possibly due to the incomplete catalytic loss of the Y157F mutation (32). We confirmed reexpression of CDO1 at protein level by Western blot analysis (Fig. 3A).

Given CDO1’s key role in the cysteine and glutathione metabolism (9, 17), we next studied ROS levels and cell viability in MDA-MB-231 cells having inducible expression CDO1-WT or CDO1-MU. ROS production was 33% higher in cells having inducible CDO1-WT expression as compared with mock cells and these cells were 20% less viable (Fig. 3B). ROS production was slightly, but not significantly, increased between mock cells or those expressing CDO1-MU protein without a change in cell viability. These results suggest that expression of enzymatic active CDO1 reduces viability of MDA-MB-231 cells through decreasing their ROS detoxification capacity.

Next, we treated 293 cells, which endogenously express CDO1, with the oxidative-damaging and glutathione-depleting agent BSO (33). Interestingly, 24 hours upon treatment with BSO, 293 cells show decreased levels of

*RReduces enzymatic activity of CDO1 to up to 95%.*
CDO1 protein and increased levels of ROS production that return to baseline at 48 hours posttreatment (Fig. 3C). This suggests that CDO1 protein level may decrease in response to increasing ROS production as an antioxidant adaptive mechanism.

CDO1-induced reduction in ROS detoxification sensitizes breast cancer cells to anthracycline treatment

Anthracyclines, such as doxorubicin, are cytotoxic ROS-generating chemotherapeutic agents (27) widely used in the treatment of breast cancer. Resistance to these agents is believed to be conferred by the upregulation of the ROS detoxification capacity in adaptation to intrinsic oxidative stress in cancer cells (27). To test whether inactivation of CDO1, as observed above, might contribute to the resistance of breast cancer cells to doxorubicin therapy, we treated CDO1 inducible MDA-MB-231 cells with different doses of doxorubicin. Cells expressing enzymatic active CDO1-WT, but not CDO1-MU, were significantly less viable at doxorubicin doses of 0.078 and 0.3125 μmol/L than mock cells (Fig. 4A and B). As expected, doxorubicin treatment increases ROS production as compared with untreated cells. Expression of CDO1-WT, but not CDO1-MU, further increased the doxorubicin-induced ROS production compared with mock cells (Fig. 4B).
To determine whether the restoration of CDO1 expression through treatment with 5-azacytidine was a viable strategy to sensitize breast cancer cells to doxorubicin therapy, we pretreated MDA-MB-231, MCF7, and T-47D cells with 5-azacytidine for 72 hours. This treatment resulted in reexpression of CDO1 and an up to 40% decreased cell viability when cells were subsequently treated with doxorubicin compared with cells not pretreated with 5-azacytidine (Fig. 5A and B). To further implicate the reexpression of CDO1 in this synergistic effect, we pretreated MDA-MB-231 cells with doxycycline-induced CDO1 expression with 5-azacytidine and subsequently with doxorubicin. We observed no difference in viability between cells that overexpressed CDO1 and were pretreated with 5-azacytidine and cells that overexpressed CDO1 and were not pretreated with 5-azacytidine (Fig. 5C and D).

Discussion

In the current study, we show that aberrant DNA methylation of CDO1 is a tumor-specific and frequent (~60%) event in breast cancer that is associated with gene silencing. We observed a stage-dependent increase in CDO1 methylation frequency that significantly correlates with disease progression and outcome. Loss of CDO1 expression by DNA methylation is also a frequent event in multiple other cancer types. In addition to other studies that uncovered CDO1 as aberrantly methylated and silenced in colorectal cancer (34) and malignant glioma (35), we found promoter hypermethylation of CDO1 in association with gene silencing in ovary, lung, pancreas, and hepatocellular cancer. We further show that CDO1 function can also be lost by other mechanisms. In hMECs, we correlated silenced expression of CDO1 with a decrease of the active H3K4me2 histone mark and an increase of the repressive H3K27me3 mark, indicative of bivalent chromatin, suggesting that a repressive chromatin structure at the CDO1 promoter can adequately suppress the expression of CDO1, similar to the poised state of embryonic stem cells (36). In addition to aberrant epigenetic regulation of CDO1 gene expression, we discovered genetic aberrations that potentially alter CDO1 function. Screening of primary breast cancers with an
unmethylated CDO1 status revealed missense mutations in 17% of these tumors and when tested for functional significance, half of these mutations predicted for protein damage. Unlike CDO1 methylation, the identified mutations within the CDO1 gene did not correlate with disease outcome, potentially due to the small number of samples screened.

Under persistent increased ROS production, cancer cells adapt to such stress to escape oxidative damage and cell death by developing an enhanced, endogenous antioxidant capacity (18, 21). We find that cells that reexpress enzymatic active CDO1 harbor more ROS and are less viable than cells expressing enzymatic impaired CDO1. Restoration of CDO1 function in breast cancer cells may shift the flux from glutathione synthesis toward cysteine catabolism resulting in a decreased antioxidant capacity that is not sufficient to keep ROS levels below a toxic threshold. Similar findings have been made by Dominy and colleagues (17). Overexpression of CDO1 resulted in reduced levels of cysteine and glutathione and in enhanced sensitivity to a glutathione-dependent stressor, suggesting that glutathione levels and cellular redox capacity change in response to CDO1 expression through the limitation of cysteine, the substrate for glutathione synthesis. On the basis of these and our data, we suggest that epigenetic silencing of CDO1 may occur in cancer cells with increased ROS production and that this event may contribute to the survival of these oxidative stressed cancer cells through an increased ROS detoxification.

It is thought that increased ROS production makes cancer cells more vulnerable to damage by further ROS insults.

Figure 5. Reactivation of epigenetically silenced CDO1 through priming with 5-azacytidine contributes to the sensitization of breast cancer cells to anthracycline treatment. A, cell viability of MDA-MB-231, MCF7, and T47-D cells primed with 5-azacytidine at doses ranging from 1 μmol/L to 5 μmol/L for 72 hours and subsequently treated with doxorubicin at doses ranging from 0.078 μmol/L to 20 μmol/L for 48 hours. Obtained values are plotted as % relative to doxorubicin-untreated cells. Group comparisons were carried out using Student t test. *, P < 0.05 for 1 μmol/L 5-azacytidine in MCF7 and T47-D cells or 2 μmol/L in MDA-MB-231 cells. **, P < 0.05 for 2 μmol/L 5-azacytidine in MCF7 and T47-D cells or 5 μmol/L in MDA-MB-231 cells. B, quantitative reexpression of CDO1 in 5-azacytidine (1 μmol/L, 2 μmol/L, or 5 μmol/L for 72 hours)-treated cells prior doxorubicin treatment is shown in fold change (log2) relative to mock-treated cells. Group comparisons were carried out using Student t test. **, P < 0.05. C, cell viability of doxycycline-induced CDO1-stable MDA-MB-231 cells (doxycycline was supplemented every 24 hours throughout the entire experiment) primed with 5-azacytidine at a dose of 2 μmol/L for 72 hours and subsequently treated with doxorubicin at a dose of 1.25 μmol/L for 48 hours. Obtained values are plotted as % relative to doxorubicin-untreated cells. As a control, cell viability was measured in CDO1-stable MDA-MB-231 cells that were not treated with 5-azacytidine. D, restoration of CDO1 protein expression in MDA-MB-231 cells 72 hours posttreatment with doxycycline and with or without 5-azacytidine was confirmed by Western blot using α-CDO1 antibody and α-β-actin as a control.
induced by exogenous ROS-generating agents such as anthracyclines (24, 26). However, an enhanced antioxidant capacity not only enables cancer cells to survive under increased ROS stress and contributes to cancer cell transformation and metastasis (37–39) but also leads to resistance to ROS-generating agents (24, 27). In this respect, we observed that MDA-MB-231 cells, upon treatment with the anthracycline doxorubicin, are more sensitive when they reexpress enzymatic active CDO1 as compared with cells which express functional impaired CDO1. This finding is particularly interesting when taking into account that hypermethylation of CDO1 is an outcome predictor in anthracycline-treated, estrogen receptor-positive, and lymph node-positive patients with breast cancer (15). Our finding, that breast cancer cells with loss of CDO1 function are less sensitive to doxorubicin treatment, provides a mechanism for the predictive value of CDO1 methylation in anthracycline-treated patients and expands our understanding of how cancer cells escape the damage of ROS-generating chemotherapeutics. Anthracyclines are key components of the treatment of patients with breast cancer and loss of CDO1 expression might be a useful marker for prediction of resistance to this therapy and for selection of patients for priming therapy with 5-azacytidine to overcome resistance. Our data support that priming with 5-azacytidine of breast cancer cells with epigenetically silenced CDO1 may sensitize them to anthracycline therapy partly through the reexpression of CDO1.

Given the inactivation of CDO1 by multiple mechanisms across multiple types of cancer, a pattern that has been observed for important tumor growth–suppressive genes, the reduced growth, viability, and ROS detoxification capacity of cells with restored CDO1 function, we suggest that CDO1 may have tumor-suppressive function and that silencing of CDO1 may contribute to the survival of oxidative-stressed cancer cells and their resistance to anthracyclines through increased ROS detoxification. Dependence of cancer cell survival has recently been shown to rely on the methylation of CDO1 as one of the driver epigenetic events (40). Our findings not only support these results, but also explore in detail the functional significance of epigenetic silencing of CDO1 during breast tumorigenesis.

Disclosure of Potential Conflicts of Interest
No potential conflicts of interest were disclosed.

Authors’ Contributions
Conception and design: N. Ahuja, J. Jeschke, H.M. O’Hagan
Acquisition of data (provided animals, acquired and managed patients, provided facilities, etc.): N. Ahuja, J. Jeschke, R. Vatapalli, M.F. Calmon, C. Nelkenbrecher, M. Van Engeland, E.W. Gabrielson, A. Winterpacht
Analysis and interpretation of data (i.e., statistical analysis, biostatistics, computational analysis): N. Ahuja, J. Jeschke, H.M. O’Hagan, R. Vatapalli, L. Danilova, L. Van Neste, I.T.G.W. Bijsmans, M. Van Engeland, A. Winterpacht
Writing, review, and/or revision of the manuscript: N. Ahuja, J. Jeschke, H.M. O’Hagan, L. Van Neste, S.B. Baylin, J.G. Herman
Administrative, technical, or material support (i.e., reporting or organizing data, constructing databases): N. Ahuja, J. Jeschke, I.T.G.W. Bijsmans
Study supervision: N. Ahuja, J. Jeschke, H.M. O’Hagan, W. Zhang

Acknowledgments
The authors thank Sharon Metzger and Theresa Sanfilippo-Carwell from the Johns Hopkins Tumor Registry for their help with clinicopathologic patient information as well as Kathy Bender and Rick Moore for administrative support.

Grant Support
This study was supported by the Susan G. Komen Foundation, German Academic Exchange Service (DAAD), and Dr. Jost Henkel Stiftung.
